Tetrafluoroethylene and ethylene monomer mixtures can undergo thermal decomposition reactions that are even more energetic than those of pure TFE. Therefore, great care must be exercised during the copolymerization of these monomers. All equipment containing the monomers in a pure state under pressure must be barricaded to prevent injury or death in the event of violent decomposition.

Copolymers of TFE and ethylene can be prepared in aqueous, nonaqueous, or mixed systems. In the last case [55], the comonomers and initiator are dissolved in the nonaqueous phase. The water acts as a heat-transfer medium and dispersant for the viscous nonaqueous phase. Aqueous polymerizations have been carried out in the presence of fluorinated surfactants such as ammonium perfluorooctanoate with manganic acids as initiators [57]. These mixtures usually also contain a chain-transfer agent and stabilizer such as ammonium oxalate. Nonaqueous polymerizations employ a fluorinated solvent (e.g., 1,1,2-trichloro-1,2,2-trifluoroethane) with a fluorinated acyl peroxide as initiator. Chain-transfer agents are added to control molecular mass. The polymerization temperature is usually between 30 and 85 °C, with pressures below 1.7 MPa.

The following four propagation reactions take place in TFE–ethylene copolymerizations:

k = rate constant; $r_1 = k_{11}/k_{12}$; $r_2 = k_{22}/k_{21}$

Reactions 2 and 3 give alternating units, while reactions 1 and 4 give nonalternating units. The ratio of the rate constants of reaction 1 to reaction 2 is designated r_1. The corresponding ratio of reaction 4 to reaction 3 is designated r_2. Low values for r_1 and r_2 signify a highly alternating copolymerization. Values for r_1 and r_2, measured at 60 °C, are 0.033 and 0.258, respectively. By using these values, it can be calculated that a 1 : 1 copolymer of TFE and ethylene, prepared at 60 °C, contains ca. 92 % alternating units. This calculated value agrees well with experimentally determined values (e.g., by high-temperature NMR studies). More highly alternating copolymers are obtained at lower temperatures. A 1 : 1 copolymer prepared at 0 °C is ca. 96 % alternating. Theory predicts that an essentially 100 % alternating copolymer can be prepared at ca. −80 °C.

The high-temperature stress–crack resistance of ETFE resins can be improved by incorporating suitable termonomers such as vinyl monomers without telogenic activity that provide at least a two-carbon branch [54–56].

The copolymers are isolated from the aqueous polymerization medium by coagulating, filtering, washing, and drying. The product is recovered from nonaqueous polymerization by evaporating the fluorinated solvent. Finishing usually includes a melt-compaction step in which the dried powders are converted into extruded pellets (molding powders).

2.5.2. Properties

Physical Properties. Alternating copolymers of TFE and ethylene have a unique crystalline lattice [58]. The unit cell, which is orthorhombic or monoclinic, has the following parameters: $a = 0.96$ nm, $b = 0.925$ nm, and $c = 0.5$ nm ($\gamma = 96°$). The calculated crystalline density of the unit cell is 1.9 g/cm^3. The molecular conformation is an extended zigzag, with the molecular packing in the orthorhombic configuration. Each molecule has four nearest neighbors with the CH_2 groups of one chain adjacent to the CF_2 groups of another. Determination of percent crystallinity of ETFE resins by X-ray techniques is difficult because of numerous imperfections in the lattice. Typical copolymers have a degree of alternation of ca. 0.88, which means a departure from alternation once every 16 carbon atoms. Crystallinity probably ranges from 40 to 60 %, depending on quench rate and conditions after molding.

The melting points of ETFE resins can vary from 200 to 300 °C [8], depending on the TFE : ethylene ratio, degree of alternation, and termonomer content. A typical commercial ETFE resin, Tefzel 200, melts at ca. 270 °C. The effect of degree of alternation on the melting point of a 1 : 1 copolymer is as follows:

Degree of alternation	*mp*, °C
0.92	280
0.96	296
(1.0)	(318)

As indicated in Section 2.5.1, the degree of alternation varies with the polymerization temperature.

In addition to the crystalline melting point, ETFE resins exhibit three second-order transitions [59]. At 1 Hz, the α-, β-, and γ-relaxations were observed at 110, −25, and −120 °C, respectively, in a quenched sample. The α- and γ-relaxations are attributed to motions of long and short segments, respectively, in the amorphous regions. The β-transition appears to occur in the crystalline regions. These transition temperatures depend on frequency. The temperature of the α-transition is 145 °C when measured at 100 Hz, and 170 °C when measured at 10^5 Hz. The γ-transition occurs at −35 °C when measured at 10^5 Hz.

Under ambient conditions, ETFE resins are insoluble in every known solvent. This precludes the measurement of molecular mass by the usual methods. However, diisobutyl adipate dissolves ETFE resins above 230 °C. A high-temperature laser light-scattering apparatus can be used to measure the weight-average molecular mass $\bar{M}_w$ of ETFE resin in diisobutyl adipate solution at 240 °C [60]. Molecular masses, $\bar{M}_w$, are obtained ranging from 5.62×10^5 to 1.13×10^6, with a polydispersity index ($\bar{M}_w/\bar{M}_n$) of ca. 1.3. The correlation between melt viscosity (in Pa · s) and $\bar{M}_w$ was shown to be

$$\eta = 1.88 \times 10^{-20} \cdot \bar{M}_{w\ 3.42}$$

The molecular mass of ETFE resins is normally specified in terms of melt-flow index (MI), measured at 300 °C in a melt rheometer; values are between 3 and 30 g/10 min.

Mechanical Properties. Modified ETFE resins are tougher and stiffer and have higher tensile strength than other TFE polymers such as PTFE, FEP, or PFA. Typical properties are given in Table 10 [61]. As wire insulation, ETFE resins exhibit excellent cut-through and abrasion resistance.

Addition of fillers enhances creep and wear resistance. Unlike other TFE polymers, ETFE can be reinforced by glass fibers. The properties of a 25 % glass-reinforced Tefzel composition, HT-2004, are shown in Table 10; it has about twice the tensile strength and heat distortion temperature of the unreinforced resin, and its flexural modulus is almost 5 times higher. Its ultimate elongation is low, which is characteristic of reinforced compositions. However, its high toughness is indicated by the high Izod impact values at room temperature, as well as at −54 °C.

The operating temperature range of ETFE resins is broad, from ca. −100 °C to at least +150 °C. This upper limit is a conservative estimate based on extensive high-temperature testing. It is the temperature at which at least half of the original properties are retained after 20 000 h exposure. The compositions with higher stress–crack resistance such as Tefzel 280 tolerate temperatures up to ca. 240 °C without cracking. Cross-linking by high-energy radiation further enhances its high-temperature mechanical properties [62]. Some radiation-cross-linked ETFE wire constructions have been rated for continuous service at 200 °C.

Electrical Properties. The ETFE resins serve as excellent insulating materials. Their dielectric constant is low (2.6) and is essentially independent of the frequency. The dielectric strength ranges from 16 – 20 kV/mm, when measured on 3-mm thick specimens, to 160 – 200 kV/mm on films 25 – 75 µm thick.

Radiation Resistance. Resistance to gamma and electron beam radiation is excellent. Properties are still useful after exposure to more than 10^6 Gy (100 Mrad). Radiation is more harmful in air than in nitrogen.

Chemical Resistance. Resistance to chemicals and solvents is also excellent. Strong acids and bases, aromatic and aliphatic hydrocarbons, alcohols, ketones, and esters have no effect on ETFE resins. Strong oxidizing acids, organic bases, and sulfonic acids attack ETFE resins to varying degrees at elevated temperatures. Certain high molecular mass esters such as diisobutyl adipate are solvents for ETFE resins above 200 °C.

Weatherability. Like other TFE polymers, ETFE resins have outstanding weatherability. Extended exposure in Florida and Arizona had no effect.

Flame Resistance. The ETFE resins are nonflammable in air. Wires insulated with ETFE resins are rated 94V–O by the Underwriters Laboratories, with a LOI of 31 %.

2.5.3. Processing

Common techniques such as injection molding, compression molding, blow molding, transfer molding, rotational molding, extrusion, and coating techniques are used for processing ETFE resins. Processing temperatures are usually 300 – 340 °C. Molten ETFE can corrode some steels, and corrosion-resistant steel such as Hastelloy C is recommended for equipment parts that come in prolonged contact with molten ETFE resins.

High extrusion rates without melt fracture can be achieved [63]. The critical shear rates for ETFE resins are at least 250 times higher than those of other TFE resins. Typical values are as follows:

Product grade	Melt-flow index, g/10 min	Critical shear rate, s^{-1}
Tefzel 210	45	12 000
Tefzel 200	8	4 800
Tefzel 280	3	4 500

Table 10. Mechanical properties of ETFE resins

Property	Tefzel 200	Tefzel HT-2004 *	ASTM
Relative density	1.70	1.86	D 792
Tensile strength, MPa	44.8	82.7	D 638

Coefficient of friction			
Static, 3.4 MPa load		0.3	
Dynamic, $u = 900$ m/s	0.4	0.3	

* 25 % Glass fiber reinforced composition.

2.5.4. Uses

The unique properties of ETFE resins make them useful in many applications. The general-purpose 200 grade is used for jacketing signal, control, communications, and power wiring for mass transport systems. It is also used for control and instrumentation wire for utilities, for critical wiring in chemical plants, and for injection-molded components such as sockets and connectors. Other products include seal glands, pipe plugs, fasteners, pump vanes, pump impellers, laboratory ware, and chemical packings. The high melt-flow 210 grade is used for extrusion coating of fine wires and injection molding of intricate shapes. The high stress–crack resistance 280 grade is used for insulating heater cables and automotive wiring and for oil-well logging cables. This resin is also used for transfer molding and injection molding of articles containing metal inserts or thick sections, and for stock shapes such as tubes and rods.

2.6. Polychlorotrifluoroethylene

Polychlorotrifluoroethylene [*9002-83-9*] (PCTFE) is a linear, high molecular mass polymer with the general formula:

It is semicrystalline (*mp* ca. 210 °C) and can be processed by conventional methods. It has good mechanical properties, chemical inertness, radiation resistance, and low vapor permeability. The quick-quenched form is optically clear; the slow-cooled form is translucent. It is supplied by Daikin Kogyo (Daiflon), 3M (Kel-F), Allied Signal (Aclar), and Ausimont (Aclon).

2.6.1. Production

Polychlorotrifluoroethylene can be polymerized to high molecular mass in bulk [64], solution [65], suspension [66] , or emulsion systems [67] using free-radical initiators. The emulsion process is carried out near room temperature over a persulfate–bisulfite redox catalyst. The polymer emulsion is coagulated by freezing or by the addition of salts. The isolated polymer is washed to remove initiator residues and dried.

The dried powders can be stabilized by the addition of phenols or salts of organic acids to help prevent discoloration and bubbling during processing. The tendency for PCTFE to become brittle during use can be reduced by incorporating a small amount (< 5 %) of vinylidene fluoride during polymerization.

2.6.2. Properties

The crystallinity of PCTFE ranges from 45 % (quick-quenched) to 65 % (slow-cooled). The molecular mass of PCTFE resin ranges from 1×10^5 to 5×10^5. The useful temperature range is between -200 and $+180$ °C. Other properties are as follows [68]:

mp	211 – 216 °C
Second-order transition (amorphous)	71 – 99 °C

Coefficient of thermal expansion	$(4-7) \times 10^{-5}\ K^{-1}$
Specific heat	$0.92\ kJ\ kg^{-1}\ K^{-1}$
Relative density	2.10 – 2.18
calcd. amorphous	2.075
crystalline	2.185
Tensile strength	
at 23 °C	30 – 40 MPa
at 100 °C	16 – 20 MPa
Elongation	
at 23 °C	30 – 80 %
at 100 °C	600 %
Flexural modulus	1000 – 2000 MPa
Hardness, Shore D	90
Dielectric constant	
at 100 Hz to 1 MHz	2.8 – 2.5
Dissipation factor	
at 1 kHz	0.023
Dielectric strength, 0.1 mm film	120 – 150 kV/mm

Resistance to attack by most chemicals is good. However, chlorinated compounds, ketones, and aromatic compounds such as benzene, toluene, and xylene swell PCTFE resins. They are impermeable to water vapor as well as other gases. They are nonflammable (LOI= 95 %), and exhibit outstanding stability to UV and gamma radiation. The coefficient of friction (like that of FEP resin) is low; antistick properties (like those of polyethylene) are excellent [69].

2.6.3. Processing

Polychlorotrifluoroethylene resins can be processed by the usual methods for thermoplastic materials such as extrusion, injection molding, and transfer molding. As with other fluoropolymers, corrosion-resistant materials should be used for equipment parts in contact with the melt. Processing temperatures are in the range of 280 – 350 °C. However, degradation begins at ca. 280 °C and so always accompanies the processing of PCTFE resins. Partial degradation does not seem to affect properties greatly, but severely degraded PCTFE becomes highly crystalline and its mechanical properties suffer. In injection molding, the mold should be heated to 70 – 130 °C. Corrosion-resistant coatings of PCTFE resins can be applied from aqueous dispersions (30 – 60 % solids) by dipping or spraying followed by drying and sintering. Coating thickness is in the range of 0.1 – 0.2 µm. Finely divided PCTFE powders (particle size < 150 µm) are used for powder coating.

2.6.4. Uses

Because of its high compressive strength, PCTFE is well suited to the construction of chemical apparatus. It is used in laboratory ware, pump parts, transparent sight glasses, flow meters, tubes, and linings. Films, wire and cable insulation, and components made from PCTFE are used in the electrical industry. Thin films are used as waterproof packaging for pharmaceuticals and expensive electronic parts.

2.7. Chlorotrifluoroethylene–Ethylene Copolymers

Copolymers of CTFE and ethylene (ECTFE resins) [*25101-45-5*] are linear, semicrystalline polymers composed of alternating monomer units:

These resins have high tensile strength, moderate stiffness, and good flex life and impact strength. Electrical properties, chemical resistance, weatherability, radiation resistance, and nonflammability are all good. The usual processing methods, such as extrusion, injection molding, and transfer molding, are employed. The resins are readily converted into fibers, filaments, films, sheets, and wire and cable insulation. Powder forms are available for the preparation of void-free, low-permeability coatings on metals by electrostatic and fluidized-bed processes. The resins are manufactured by Ausimont (Halar).

2.7.1. Production

Ethylene and CTFE can be copolymerized by the techniques used for other fluoroolefins. However, to prepare commercially useful products, the copolymerization must be carried out at low temperature (preferably 10 °C or below). A typical polymerization employs a mixture of CTFE and ethylene in water at 10 °C, with trichloroacetyl peroxide as catalyst and chloroform as chain-transfer agent [70]. Under these

conditions, the copolymerization takes place in the condensed CTFE phase. Water acts as a dispersant and heat-transfer medium. Copolymerization has been carried out at even lower temperatures (between −40 and −80 °C), using oxygen-activated trialkylborons as initiators [71]. Terpolymers with improved thermal stress–crack resistance are prepared similarly. Termonomers for thermal stress–crack-resistant compositions include perfluoro(alkyl vinyl ethers) [54], perfluoroalkylethylenes [72], and 2-trifluoromethyl-3,3,3-trifluoroprop-1-ene [56]. The same techniques are used for isolation from the polymerization media as with other fluoropolymers.

2.7.2. Properties

Physical Properties. The crystallinity of commercial ECTFE resins is in the 50 – 60 % range. X-ray diffraction studies indicate that the unit cell of the alternating copolymer is hexagonal, with a chain repeat distance of $c = 0.50$ nm [70]. The molecular conformation is an extended zigzag, with an ethylene unit on one chain adjacent to a CTFE unit on another chain.

The melting point of an ECTFE copolymer is a function of the molar ratio and the degree of alternation of the two monomers. Commercial ECTFE resins are 1 : 1 copolymers of CTFE and ethylene, 80 – 90 % alternating. They have melting points in the range of 235 – 245 °C. A 1 : 1 copolymer prepared at −80 °C, essentially 100 % alternating, melts at 264 °C [71]; second-order transitions are observed at 140, 90, and −65 °C. The α- and γ-transitions are associated with the motion of chain segments in the crystalline regions, whereas the β-transition seems to be associated with the amorphous region.

The number-average molecular mass ($\bar{M}_n$) of ECTFE resins, determined by osmometry at 150 °C, ranges from 1×10^5 to 5×10^5; other properties are as follows:

mp	236 – 246 °C
Coefficent of thermal expansion	5×10^{-5} K^{-1}
Relative density	1.7
Tensile strength	50 – 65 MPa
Elongation	150 – 250 %
Flexural modulus	1800 – 2500 MPa
Hardness, Shore D	78
Izod impact strength	
at 23 °C	no break
at −40 °C	2 – 3 J/m
Dielectric constant (ASTM D 150, 60 Hz to 1 kHz)	2.55 – 2.60
Dissipation factor (ASTM D 150)	
at 60 Hz	< 0.005
at 1 MHz	0.0024
Dielectric strength 0.2 mm film	80 – 90 kV/mm
Volume resistivity	$> 10^{15}$ Ω·cm

Mechanical Properties. The ECTFE resins are tough, moderately stiff, and creep resistant. They are usable over a broad temperature range (−100 to +150 °C). Abrasion resistance and the heat distortion temperature are good and can be enhanced with fillers.

Chemical Resistance. Both ECTFE and PCTFE resins are similar in chemical resistance. They exhibit good stability toward acids, bases, and halogens. There are no known solvents below 120 °C, but amines, esters, and ketones can attack ECTFE resins, especially when warm. These resins have excellent barrier properties to water vapor and other gases. In this respect they are superior to the perfluorinated plastics.

Weatherability and Radiation Resistance. Like most fluoropolymers, ECTFE resins exhibit outstanding weathering resistance. They also resist high-energy gamma and beta emission. The polymer retains useful properties after absorbing more than 10^6 Gy (100 Mrads) of radiation. Cross-linking by exposure to low doses 50 – 150 kGy (5 – 15 Mrads) enhances the high-temperature mechanical properties [62].

Flame Resistance. The ECTFE resins are nonflammable; they burn when exposed to a flame, but are self-extinguishing when the flame is removed. They are nondripping and form a char; the limiting oxygen index (LOI) is 64 %.

2.7.3. Processing

The standard processing methods for thermoplastics, such as extrusion, injection molding, and transfer molding, are employed to process ECTFE. Extrusion is used to manufacture tubing, hose, and wire and cable insulation. Temperatures from 260 to 300 °C can be used, but

should be kept as low as possible to prevent degradation. Extrusion of ECTFE resins is possible at high rates without degradation. Like other fluoropolymers, molten ECTFE resins can be corrosive. A corrosion-resistant steel such as Hastelloy-C is recommended for metal surfaces in contact with the molten polymer. In injection molding of ECTFE resins, the melt temperature should be from 260 to 300 °C; for best results, the mold should be heated to 60 – 100 °C. Metals are coated by powders of average particle size below 150 µm using an electrostatic or fluidized-bed process. Coatings of 1 mm or thicker can be obtained free of voids and cracks.

2.7.4. Uses

The principal use of ECTFE resin is in flame-resistant wire and cable insulation [73]. Monofilament made from ECTFE resin is used in the manufacture of chemical-resistant filters and screens. Other applications include coatings and linings for chemical process equipment. Roto-molded tanks and containers made from ECTFE resins are used to store corrosive chemicals, e.g., nitric and hydrochloric acids. Extruded sheet is used for thermoforming various products, such as battery cases for heart pacemakers. Tubing made from ECTFE resin is used in laboratory and some automotive applications.

2.8. Poly(Vinylidene Fluoride)

Poly(vinylidene fluoride) [*9002-85-1*] (PVDF) is a linear, high molecular mass, semicrystalline polymer that can exist in three distinct crystalline forms and has the following structure:

$$-(CH_2CF_2\text{-})_n-$$

The alternating CH_2 and CF_2 groups create a dipole that confers solubility in highly polar solvents such as dimethylformamide and dimethylacetamide. In addition, PVDF has a high dielectric constant and exhibits piezoelectric properties under certain conditions. It has excellent resistance to abrasion, stress fatigue, and cold flow. Like PTFE and TFE copolymers, it has outstanding weatherability. It also exhibits excellent resistance to gamma and beta radiation. The usable temperature range is from ca. −40 to +150 °C. The resins are processible by extrusion, injection molding, and other molding techniques. Copolymerization with HFP (< 15 %) improves processibility, flexibility, and impact strength.

Uses for PVDF resins include durable finishes for exterior metal siding, electrical insulation, and chemical process equipment. The manufacturers are Pennwalt Corp. (Kynar), Solvay & Cie (Solef), Dynamit Nobel (Dyflor), Kureha Chemical Co. (Kureha KF), and Daikin Kogyo (Neoflon VDF).

2.8.1. Production

Vinylidene fluoride (VDF) can be polymerized by a variety of free-radical initiators, but the preparation of a commercially useful product requires the correct choice of initiator, dispersing agent, and reaction medium. In the first commercially successful process, developed by Pennwalt in the mid-1960s, VDF is polymerized in water at 120 – 130 °C and ca. 6.2 MPa with di-*t*-butyl peroxide as initiator [74]. Other successful processes use peroxy dicarbonates and peroxy esters as initiators [75]. Vinylidene fluoride can also be polymerized in aqueous emulsion at 80 °C and 5.2 MPa, using disuccinic acid peroxide as initiator and a perfluorocarbon acid as emulsifier. Polymerization in nonaqueous media using fluorocarbon acyl peroxides as initiators has also been reported [76].

Vinylidene fluoride–hexafluoropropene copolymers are prepared by an emulsion process, using a fluoroalkyl surfactant and CCl_3F as chain-transfer agent [77].

The products are isolated from the polymerization mixtures by the procedures described previously for other fluoropolymers.

Barium and strontium salts have been added to PVDF to improve its thermal stability.

2.8.2. Properties

Physical Properties. Poly(vinylidene fluoride) has a highly regular structure, with most VDF units joined head-to-tail and with ca. 5 % of the monomer units joined head-to-head. Crystallinity is between 40 and 60 %; three different crystalline forms exist.

In phase I (β-form), the polymer crystals are orthorhombic and the molecules adopt a planar zigzag conformation. In phase II (α-form) the crystals are monoclinic and the molecules adopt a gauche-trans-gauche-trans conformation. In phase III (γ-form), the crystals are also believed to be monoclinic, but the molecules adopt a planar zigzag conformation. Slow or rapid cooling of polymer from the melt yields only phase II. Conditions for converting one form to another have been established [78].

Because of its polymorphism, the melting point of PVDF is not precisely defined (154 – 184 °C). The melting point of the more common phase II form is ca. 170 °C; a glass transition temperature is observed at −40 °C. Properties of PVDF resin are shown in Table 11.

Mechanical Properties. Yield strength of PVDF is higher and elongation is lower than those of ETFE and ECTFE at room temperature. Modulus is similar but impact strength is lower. Modification with HFP (Solef 11010 or Kynar Flex 2800) lowers the modulus, but increases elongation and impact strength.

Electrical Properties. A high dielectric constant and dissipation factor impair the utility of PVDF as a primary wire and cable insulation. However, these "poor" electrical properties allow the production of PVDF films with their piezoelectric and pyroelectric properties [79]. These films are prepared from extruded films in the phase I (β-form) conformation, obtained by stretching the film as it is extruded; ultrapure polymer is required. Both surfaces of the film are metallized, and it is then subjected to a high voltage, which leaves it permanently polarized. Such films generate a voltage when stretched or compressed (piezoelectricity) or heated (pyroelectricity).

Chemical Resistance. Resistance of PVDF to halogens, most inorganic acids and bases, alcohols, halogenated hydrocarbons, and aromatics is good. It is, however, soluble in polar solvents such as acetone and ethyl, butyl, and amyl acetate.

Weather and Radiation Resistance. Resistance to UV light is excellent (no effect after 5000 h exposure in Weather-O-Meter). Tolerance to ionizing radiation is very high. Low radiation doses of 20 – 150 kGy (2 – 15 Mrads) cause cross-linking, which enhances the high-temperature modulus of PVDF.

Flame Resistance. When exposed to flame, PVDF is nonflammable and nondripping; it is self-extinguishing after the flame is removed. The limiting oxygen index (LOI) is 44 %.

2.8.3. Processing

Poly(vinylidene fluoride) can be processed by the usual techniques for thermoplastics such as extrusion and transfer, injection and compression molding. Metal coatings are applied from organisols (mixtures of resin and solvent) in a process called coil coating. Typically, the organisol is applied to coil stock of steel or aluminum. The film is formed on the metal surface as the solvent evaporates. In extrusion, attention should be paid to the elimination of dead spots where degradation of the polymer can start. The temperature should be between 215 and 270 °C. Similarly, in injection molding, the melt temperature should be between 200 and 270 °C. Runnerless molds are recommended.

2.8.4. Uses

An important use for PVDF resin is as a coating for metallic roofing, window frames, panel siding, and other construction units. It is also used as wire insulation in the aircraft and electronics industries. Heat-shrinkable tubing made from PVDF resin forms "solder sleeves" that are used in the electronic, aerospace, and aircraft industries. It is used on a large scale for solid PVDF pipe and fittings and as a liner for pipes and valves. Piezoelectric PVDF films are very sensitive transducers with various applications [80].

2.9. Poly(Vinyl Fluoride)

Poly(vinyl fluoride) [*24981-14-4*] (PVF) is a high molecular mass, semicrystalline polymer with a melting point of 185 – 210 °C and the following structure:

Table 11. Properties of PVDF resins

Property	Kynar PVDF	Kynar Flex 2800	Solef 11010
Relative density	1.76	1.78	1.77
Tensile yield, MPa	35.9	23.4	30.8
Tensile strength, MPa	35.9	41.4	24.8
Elongation, %	37	525	430
Tensile modulus, MPa	1503	414	1000
Flexural modulus, MPa	1393	552	1000
Dielectric constant			
at 1 kHz	9		
at 1 MHz	8		
Dissipation factor			
at 1 kHz	0.014		
at 1 MHz	0.18		
Volume resistivity, $\Omega \cdot$ cm	2×10^{14}	8×10^{13}	6×10^{14}

It is considered a thermoplastic but cannot be processed by conventional thermoplastic techniques because it is unstable above its melting point. It can be fabricated into films by mixing with "latent" solvents and extruding at a temperature below the melting point. (Dissolution in "latent" solvents takes place at an elevated temperature below the melting point of the PVF.) Films made from PVF have exceptional resistance to sunlight, chemical attack, and water adsorption. They are also extremely tough and have good abrasion resistance. These unusual properties make PVF highly suitable for outdoor coatings or laminates. Films of various tensile modifications and thicknesses are available with adhereable and nonadhereable surfaces. These films are manufactured by Du Pont under the Tedlar trade name.

2.9.1. Production

Vinyl fluoride is polymerized by free-radical processes like those used for other fluoropolymers. It is, however, more difficult to polymerize than TFE or VDF and requires higher pressures [81]. Polymerization is carried out in aqueous media between 50 and 150 °C at a pressure of 3.4 – 34.4 MPa. The usual catalysts are peroxides and azo compounds. A continuous process employs water, VF, and catalyst at 100 °C and 27.5 MPa [82]. Polymers have also been prepared at lower temperatures (−30 to +55 °C) using oxygen-activated trialkylboron catalysts [83]. The polymerization temperature affects the crystallinity and the melting point of the product; higher temperatures also increase branching.

2.9.2. Properties

Physical and Mechanical Properties. The monomer units in PVF are predominantly head-to-tail, with 12 – 18 % head-to-head [84]. The proportion of head-to-head units decreases with decreasing polymerization temperature. Conversely, randomness increases with increasing polymerization temperature.

The number-average molecular mass of PVF resin ranges from 7.6×10^4 to 2.34×10^5, the weight-average molecular mass from 1.43×10^5 to 6.54×10^5. The ratio of weight-average to number-average molecular mass is 2.5 : 5.6 [85].

The melting point of PVF varies with polymerization temperature, but is in the range of 185 – 210 °C. Torsion-pendulum studies indicate that PVF has second-order transitions at +41 °C and −20 °C. The temperature range for continuous use is −70 to +110 °C. The mechanical (ASTM D 882 and 1004) and physical properties of PVF film follow [86], [87]:

mp	185 – 190 °C
Relative density	1.38 – 1.57
Tensile strength	48 – 120 MPa
Elongation	115 – 250 %
Tensile modulus	1700 – 2600 MPa
Impact strength	10 – 22 kJ/m
Tear strength	174 – 239 kJ/m
Coefficient of thermal expansion	5×10^{-5} K^{-1}
Dielectric constant, 1 MHz	4.8
Dielectric strength, 0.1 mm film	120 – 140 kV/mm

Chemical Resistance. Poly(vinyl fluoride) is insoluble in ordinary solvents below 100 °C. At higher temperature, it is soluble in polar solvents such as amides, ketones, tetramethylene sulfone, and tetramethylurea.

Films show good resistance to acids and bases at room temperature. The resistance to aliphatic (petroleum), aromatic, and alcoholic liquids is also very good. Acetone attacks PVF, especially when warm.

Weather and Radiation Resistance. Films have excellent light and weather resistance, showing no change after 10 years outdoor exposure. They are transparent to both UV and visible light. A 25-μm thick film has over 90 % transmission between 400 and 1400 nm and over 80 % between 230 and 400 nm.

In addition, PVF films show good resistance to high-energy radiation. Usable properties are retained up to 1 MJ/kg exposure to electron beam radiation.

2.9.3. Processing

The polymer is dissolved in a "latent" solvent. Pigments, stabilizers, and plasticizers can be added to the PVF organosol before extrusion. The organosol is extruded into film, and the solvent is evaporated and recovered. The film can be oriented in varying degrees to achieve different levels of tensile and tear strength. Exposure to such treatments as corona discharge or alkali metal in liquid ammonia solution imparts adhesiveness.

2.9.4. Uses

Poly(vinyl fluoride) films are laminated to sheets of metal with special adhesives. The laminates are used for exterior siding on industrial and residential buildings. Pigmented films can be made in any color. Films can also be laminated to hardboard, paper, vinyl, polystyrene, polyurethane, and other substrates. These laminates are used for wall coverings, aircraft cabin interiors, pipe covering, duct liners, as well as other applications. A weather-resistant PVF barrier is also resistant to abrasion, chemicals, solvents, and staining. Another application for PVF film is as a release sheeting in the molding of phenolic, epoxide, and polyester plastics, and as a release film for bag molding. It does not become brittle and strips easily from the mold. Toughness is maintained at elevated temperatures at all degrees of humidity and in contact with common solvents. The film has been used for solar stills because of its high transparency and resistance to solar radiation.

3. Fluoroelastomers

3.1. Introduction

Fluorine-containing elastomers are designed to maintain rubber-like elasticity in extremely severe environments at high temperature and in contact with various chemicals. Their primary use is in seals, where they function to prevent leakage after prolonged compression. Fluoroelastomers are rarely subjected to tension, and then only at modest elongations. Technologically important fluoroelastomers can be divided into two groups: (1) the fluorocarbon elastomers discussed here and the fluorosilicones developed in the 1950's, and (2) the fluoroalkoxyphosphazines introduced in 1975, which represent only a very small share of the fluoroelastomer market.

At service temperatures above 0 °C, noncross-linked elastomers are highly viscous, incompressible liquids. To prevent permanent flow deformation under an imposed force and to develop reversible elastic properties, these flexible macromolecules must be cross-linked. The restoring force that acts on a uniaxially or biaxially deformed elastomeric network is based on the lower entropy of the extended, and hence, oriented, chains rather than on an increase in enthalpy. In general, cross-linking is performed chemically by vulcanization to produce thermoset elastomer networks. However, physical cross-linking by crystallization of hard segments in segmented or grafted copolymers can also provide a network structure in so-called thermoplastic elastomers. The few known thermoplastic fluoroelastomers have a much lower high-temperature service ceiling than the thermoset elastomers, nevertheless they possess certain advantages in processibility because they can be reversibly cross-linked. Furthermore,

they generally yield less extractable material because they contain no curatives.

To achieve high solvent resistance and thermal stability in fluorocarbon polymers, low-temperature flexibility and a high fluorine content are desirable; these requirements conflict to some extent. Low-temperature flexibility is governed by the glass transition temperature (T_g), which depends mainly on the conformational flexibility of individual chain elements. Therefore, if the various conformational states can be interconverted more freely, the T_g is lower and the low-temperature performance is better.

If linear perfluorocarbon macromolecules are cross-linked, they do not exhibit elastomeric properties at ambient or lower temperatures because of the severely restricted rotation about the carbon–carbon bonds and the consequent lack of alternative conformations. Thus, a tetrafluoroethylene (TFE) homopolymer cannot be an elastomer even if it has no crystallinity in the temperature range mentioned. Alternating difluoromethylene and methylene groups are the principal structural feature of poly(vinylidene fluoride). This polymer has a sufficiently low T_g (−40 °C) for elastomeric properties, but very strong intermolecular forces cause crystallization (latent heat of fusion ΔH_f, 6 kJ/mol; *mp,* 165 °C) [88] and, thus, restrict conformational freedom. Because of these properties of the homopolymers, most fluorocarbon elastomers are based on structures that interrupt this crystallinity and yet benefit from the low T_g of short vinylidene fluoride (VDF) sequences. For example, copolymerization of hexofluoropropene (HFP) and VDF in the molar ratio of 3.5 : 1.0 produces a fluoroelastomer [*9011-17-0*] with no crystallinity and a T_g of ca. −20 °C. This composition (60 wt% VDF) is the basis of the fluorocarbon elastomer industry:

Copolymerization of a monomer that produces a crystalline but low-T_g polymer with a monomer that has a relatively bulky substituent produces an elastomer by interrupting the homopolymer crystallinity. Thus, copolymerization of VDF with HFP, HFP–TFE, chlorotrifluoroethylene (CTFE), perfluoro(methyl vinyl ether) (PMVE), or PMVE–TFE produces elastomers, copolymerization of TFE with PMVE or propylene also yields elastomers.

Fluoroelastomers with a higher fluorine content and superior low-temperature properties can be prepared by copolymerization with PMVE or similar perfluorinated vinyl ethers, although at greatly increased cost. With the exception of the perfluoropolymer poly(TFE–PMVE), fluorocarbon elastomers generally contain hydrogen and are also known as hydrofluoroelastomers.

The low-temperature properties of fluorosilicones (→ Silicones) and fluoroalkoxyphosphazenes (→ Inorganic Polymers) are superior to those of elastomers with backbones that consist only of carbon atoms substituted by hydrogen, fluorine, chlorine, fluoroalkyl groups, or simple fluoroalkoxy groups. Their outstanding chain flexibility is a result of the alternating oxygen or nitrogen backbone atoms. The low degree of substitution results in low activation energies for rotation about these atoms and adjacent chain atoms and, therefore, in low glass transition temperatures. However, fluorosilicones and fluoroalkoxyphosphazenes contain less fluorine than fluorocarbon elastomers; therefore, their solvent resistance and high-temperature stability are inferior.

Commercial fluorosilicone elastomers are polydimethylsiloxane homopolymers in which one methyl substituent of each silicon atom is replaced by a 3,3,3-trifluoropropyl group:

[*25791-89-3*]

Commercial fluoroalkoxyphosphazene elastomers are produced by replacing the chlorine in dichlorophosphazene polymers by fluorocarbon alkoxides [89]:

[*37002-15-6*] (T_g = −77 °C)

The service temperature range and fluorine and hydrogen content of fluoroelastomers are given in Table 12.

Table 12. Service temperature, fluorine content, and hydrogen content at fluoroelastomers

Type	Service temperature, °C ∗	Fluorine, %	Hydrogen, %
Hydrofluorocarbon			
VDF−HFP	−18 to 210	66	1.9
VDF−HFP−TFE	−12 to 230	66 – 69.5	1.1 – 1.9
VDF−PMVE−TFE	−27 to 230	64 – 66.5	1.1 – 1.7
TFE−P	5 to 200	54	4.3
Perfluorocarbon	− 0 to 260	73	0
Fluorosilicone	−65 to 175	37	4.5
Fluoroalkoxyphosphazene	−65 to 175	55	1.4

∗ Temperature of elastomeric side of glass transition to maximum temperature for continuous service.

3.2. Elastomers Based on Vinylidene Fluoride

Dipolymers of vinylidene fluoride (VDF) and chlorotrifluoroethylene (CTFE) [*9010-75-7*] prepared by M. W. Kellogg under contract with the United States Army Quartermaster Corps were first described in 1955 [90–92]. After vulcanization, this fluoroelastomer (Kel-F) exhibited previously unattainable resistance to heat and solvents. However, it was soon surpassed by an even more stable fluoroelastomer, a dipolymer of VDF and hexafluoropropene (HFP) [*9011-17-0*] , that was described in 1956 and commercialized by Du Pont in 1958 under the Viton A trade name [93–95]. In 1960, Du Pont introduced a TFE-containing terpolymer [*25190-89-0*] (Viton B) that was even more thermally stable and solvent resistant than Viton A [96], [97]. The Minnesota Mining and Manufacturing Co. (3M), who had acquired the fluorocarbon polymer assets of M. W. Kellogg, introduced a VDF−HFP copolymer under the Fluorel trade name in 1958 and continued its manufacture after 1962 under license from Du Pont.

Elastomeric copolymers of VDF and 1-hydropentafluoropropene [*32552-63-9*] and a TFE-containing terpolymer [*29830-35-1*] were introduced by Montecatini–Edison during the 1960s [98–100]. However, these polymers, sold under the Tecnoflon name, lacked the stability of similar HFP compositions, and were replaced by HFP analogs as early patents for poly(VDF–HFP) and poly(VDF–HFP–TFE) expired. Daikin Kogyo began production of VDF-based fluoroelastomers (Dai-el) in 1970 under license from Du Pont. A dipolymer, known as SKF-32 and produced in the Soviet Union, is not traded on the world market.

Trademarks and manufacturers of commercial VDF-based fluoroelastomers are shown in Table 13.

Table 13. Commercial VDF-based elastomers

Copolymer	Trade name	Manufacturer
VDF−HFP	Viton	Du Pont
	Fluorel ∗	3M
	Tecnoflon	Montefluos
	Dai-el ∗	Daikin
VDF−HFP−TFE	Viton ∗	Du Pont
	Fluorel ∗	3M
	Tecnoflon	Montefluos
	Dai-el ∗	3M
VDF−PMVE−TFE	Viton ∗∗	Du Pont

∗ Also available with proprietary cure site for peroxide curing.
∗∗ Contains perfluoro(methyl vinyl ether) and proprietary cure site; can be cured only with peroxide.

3.2.1. Production

Vinylidene fluoride based elastomers are usually prepared by continuous or batch polymerization in aqueous emulsion with free-radical initiators. Although free-radical solution polymerization is also possible at practical polymerization temperatures, chain transfer keeps molecular mass low in the solvents that must be used. The monomers are mainly derived from fluorocarbon refrigerants and their intermediates, and are relatively inexpensive because they are manufactured on a large scale.

Typical aqueous emulsion polymerizations are conducted at 5 – 7 MPa and 100 – 120 °C [101]. Commonly used initiators are inorganic peroxides such as ammonium persulfate; however, organic peroxides and redox systems are also used, especially at low temperature where the thermal decomposition of persulfate is slow. Emulsifying agents, when required, must be

compatible with the highly reactive fluorocarbon radicals of growing polymer chains; salts of fluorocarbon acids are used to prevent chain transfer. Molecular mass is regulated by controlling the rate of initiation and polymerization; chain-transfer agents may also be useful. Such agents generally have reactive carbon–hydrogen or carbon–halogen bonds; diethyl malonate and carbon tetrachloride are typical. Buffers control the pH of the polymerization and stabilize the emulsification system. Molecular mass ($\bar{M}_w$) ranges from 1.5×10^5 to 10^6.

In batch polymerization, the ingredients are heated in the reactor and the reaction is allowed to proceed until the pressure drop corresponds to the desired extent of reaction. In semibatch polymerizations, monomers can be added continually under pressure at rates that correspond to their consumption, providing better control of copolymer composition.

In a continuous process, water, monomers, initiator, and other components are fed to the reactor while polymer latex is removed at a corresponding rate. Composition and molecular mass can be precisely controlled. Monomers and other reactants of widely ranging reactivities can be used without undue variation in polymer structure. Unreacted monomers are evaporated from the latex and recycled.

In either process, the latex from the reactor is coagulated by the addition of salts or acids. The polymer crumb is filtered or centrifuged and washed to remove coagulant and water-soluble residues. After being dried, it may be mixed with curing (cross-linking) agents. The finished product is packaged as extruded pellets and lumps or in milled sheets.

3.2.2. Properties

Heat Resistance. Vinylidene fluoride based polymers are the largest group of fluoroelastomers in terms of production volume and variety. Their properties (Table 14) serve as a standard for comparing other fluoroelastomers that may be superior in certain respects such as lowtemperature flexibility (fluorosilicones and fluoroalkoxyphosphazenes), but are less satisfactory at high temperatures and in destructive fluids. An exception is the poly(TFE–PMVE–X) perfluoroelastomer (where X = cure-site monomer), which is virtually chemically inert and extremely stable to heat and oxidation. Vinylidene fluoride based elastomers can be used continuously at temperatures as high as 230 °C, depending on polymer type and formulation. Dipolymers retain over 50 % of their tensile strength for more than 1 year at 200 °C or 2 months at 260 °C. Functionalized hydrocarbon elastomers that are considered to be resistant to oil, such as nitrile or acrylate rubber, lose 50 % of their elongation aging at 150 °C for 10 and 25 days, respectively; in comparison VDF-based fluoroelastomers retain over 95 % of their elongation after 1 year at 200 °C [102].

Table 14. Physical properties of VDF-based fluoroelastomers

Property	Range	ASTM
Relative density of raw polymer	1.77 – 1.91	
Tensile properties		
100 % modulus, MPa	2 – 15	
Tensile strength, MPa	5 – 20	
Elongation at break, %	50 – 500	
Hardness, durometer A	60 – 95	
Compression set ∗, %		D-395
70 h at 25 °C	10 – 15	
70 h at 200 °C	10 – 40	
1000 h at 200 °C	50 – 70	
Low-temperature properties		
Clash–Berg torsional-stiffness temperature (69 MPa), °C	−31 to −5	
Retraction temperature (TR-10), °C	−31 to −6	D-1329
Brittle point, °C	−51 to −34	D-746

∗ Method B, 24.5 × 3.5 mm O-rings.

In the retraction-temperature test (Table 14) (ASTM D-1329), an elastic article is stretched at room temperature, cooled to a specified lower temperature, and allowed to retract. In general, it does not reach its original length but remains larger. The percent increase in length is denoted as TR, e.g., TR–10 for a 10 % increase.

Fluid and Chemical Resistance. The resistance of VDF–HFP and VDF–HFP–TFE elastomers to petroleum-based fuels and oils is excellent. Certain lubricants, however, contain additives that disperse sludge and inhibit metal corrosion, but are highly basic or decompose to basic products that attack the elastomer. Therefore, the performance of the fluoroelastomer must be evaluated in contact with the particular fluid containing its proprietary additives. Formulators of oil additives should examine not only lubricant stabilization and metal protection [103–

105], but also the behavior of seals. Fluoroelastomers to be used with hydrocarbon–alcohol fuels (gasohol) must be chosen with care [106]. A VDF–TFE polymer of 69.5 % fluorine content is used in methanol blends to prevent excessive swelling. This polymer is also recommended for certain phosphate ester based hydraulic fluids.

In contact with aromatic solvents, 68 or 69.5 % fluorine polymers give the best performance. Alcohols other than methanol do not greatly swell VDF-based elastomers despite their polar nature, but blends of alcohols and other fluids may act differently. Polar solvents that are not hydrogen bond donors, but only acceptors, tend to have a high affinity for these elastomers and may actually dissolve raw polymer or destructively swell vulcanizates. Examples of such solvents are low-boiling ketones and esters (acetone, methyl ethyl ketone, ethyl acetate), amides (*N,N*-dimethylformamide, *N,N*-dimethylacetamide), and ethers (tetrahydrofuran, 2-methoxyethyl ether). Mixtures that contain substantial amounts of these solvents cannot be used with this group of fluoroelastomers.

In addition to the destructive action of highly swelling solvents, the vulcanizate may be attacked chemically. Dehydrofluorination by primary and secondary aliphatic amines occurs readily and is the basis of amine cross-linking. The resulting unsaturated bonds are susceptible to nucleophilic attack, which can lead to cross-linking and embrittlement. With amine-based curing systems, which are seldom used, dehydrofluorination is a controlled process; however. uncontrolled exposure to soluble aliphatic amines and other soluble strong organic bases degrades these vulcanizates and must be avoided. Resistance to aqueous alkali is far greater, but will eventually cause surface cracks and failure. Phase-transfer catalysts such as quaternary ammonium ions accelerate degradation by aqueous alkali.

Resistance to aqueous acids is generally good, especially if acid acceptors such as calcium hydroxide, magnesium oxide, or calcium oxide are not present in large amounts. Lead-based acid acceptors such as sublimed litharge and dibasic lead phosphite are used for optimal acid resistance; these must be handled by safe procedures. The use of high-concentration dispersions of litharge in fluoroelastomers prevents litharge dust problems during compounding. Such dispersions must not be heated above 200 °C to avoid exothermic decomposition to metallic lead, which occurs with an 80–20 litharge–fluoroelastomer mixture [107].

Other Types of Resistance. Ozone resistance and weatherability are excellent [108] and permeability to gases is low. Vulcanizates can be formulated to be self-extinguishing or nonflammable. Abrasion resistance varies. Resistance to β-radiation is moderate and independent of VDF–copolymer composition. Radiation doses are cumulative and a total exposure to $10^4 - 10^5$ J/kg produces moderate to severe effects on physical properties. Radiation failure occurs by embrittlement rather than chain cleavage [109].

3.2.3. Processing

Formulation. Elastomer processing generally includes formulation. Optimum conditions must also be selected to provide the properties desired after vulcanization (cross-linking). The composition (in parts per hundred of rubber, phr) of a typical fluorocarbon elastomer follows:

Fluorocarbon elastomer	100
Acid acceptor (inorganic base)	3 – 15
Filler	0 – 50
Curing agents (sometimes included before formulation)	0 – 5
Processing aids	0 – 3

In O-ring formulations (Table 15), compression-set resistance is of critical importance, because sealing can be maintained only if the O-ring can retain some tendency to regain its uncompressed dimensions. Higher molecular mass and thus higher viscosity usually display better compression-set resistance. The choice of curing systems is also important because the stability of the cross-links limits the stability of the elastomer network. The bisphenol curing system offers greater compression-set resistance than the peroxide curing system and is generally preferred for O-ring and similiar sealing applications. However, peroxide-cured stocks usually have better resistance to steam and acids and are often specified [101].

Table 15. Fluoroelastomer molding and O-ring compounds

	General-purpose molding	O-ring material

In formulations for molded articles (Table 15), compression-set resistance is usually sacrificed in favor of elongation. A lower cure state and greater elongation are achieved by using less cross-linking agent or a lower molecular mass polymer; this has the important effect of reducing viscosity and increasing mold flow. High elongation is often required, because many mold designs require substantial elongation of the hot vulcanizate to facilitate removal from the mold. The tear strength at the demolding temperature, which increases with increasing elongation, is also an important processing requirement, especially if adhesion to the mold is high. If these processing requirements for elongation have been satisfied, molded articles are not usually used in tension, but rather under slight compression, although some elongation may occur during installation.

Vinylidene fluoride based elastomers are available in a range of molecular masses that correspond to Mooney viscosity values of 0–160 (ML-10, 121 °C). (The Mooney viscosity is a measure of polymer plasticity.) The choice of fillers and acid acceptor in fluoroelastomers has a major effect on viscosity and, therefore, influences processibility and properties after vulcanization [110], [111].

Specialized polymers can be compounded for exceptional resistance to fluids and low-temperature flexibility (Table 16). The PMVE polymer exhibits the best low-temperature properties of any commercial fluorocarbon elastomer [112]. Excellent resistance to methanol and methanol–fuel blends are characteristic of compounds based on the polymer containing 69.5 % fluorine [113].

Mixing. Standard rubber compounding equipment and techniques are used to mix VDF-based fluoroelastomer stocks. Rubber mills are suitable for most viscosity grades, although some reduction in molecular mass may occur when high-viscosity polymers are cold milled and the clearance between rolls is small. Banbury and other internal mixers are also suited for preparing precompounds that also contain fillers, inorganic acid acceptors, and processing aids. Producers commonly supply precompounds that are then fully compounded by a custom-mixing firm or by the molder.

Molding. Compression molding is usually the most economical and flexible form of vulcanization. When extruded or cut preforms are used, the amount of mold flashing is kept to a minimum and higher viscosity polymers can be used because mold-flow requirements are low.

Transfer molding requires lower viscosities than compression molding because the compound must flow more easily. Bisphenol-curable compounds are suited to transfer molding because of their processing safety (premature vulcanization during processing is low). Only small articles are normally produced by this technique.

Injection molding requires a higher capital investment than compression or transfer molding and is usually less labor intensive. Injection molding is used increasingly and is justified in large-scale production where labor savings offset equipment costs and increased waste from mold filling channels. Newer mold designs reduce this waste. Compound formulation is critical for injection molding because high flow rates and compound safety are required. Compounds must be characterized rheologically before processing conditions can be established. Injection molding of thermoset elastomers is much more demanding than injection molding of thermoplastics or thermoplastic elastomers because the

former case entails irreversible chemical reactions that increase viscosity and create cross-links during hot flow; in the latter case, the polymer flows easily in the melt and is simply cooled or crystallized in the mold.

Molding cycles are usually 1 – 5 min. at 160 – 200 °C and depend on the size of the article because of heat transfer limitations. In injection molding, however, frictional or shear heating, produced by high flow rates through small mold orifices, raises the temperature in the mold significantly. In large moldings produced by compression or injection molding, the heat of reaction of the vulcanization must also be considered.

Extrusion. Fluorocarbon elastomers can be shaped and cured by extrusion. The fully compounded stock is continuously forced through a shaping die at the end of an extruder below the curing temperature. The continuous extrudate, which may be hose or tubing, rod stock for spliced O-rings, or profile stock for cut gaskets, is rolled up or otherwise placed in a steam autoclave, where curing takes place at ca. 160 °C. Extruded stock is also used to cut preforms for subsequent curing by compression or transfer molding.

Postcuring. Fluorocarbon elastomers are usually postcured to develop optimum physical properties, such as compression-set resistance and tensile strength [114]. The postcure cycle subjects a press-cured article to circulating air at atmospheric pressure at 200 – 260 °C for 12 – 24 h. Small amounts of volatile substances are removed, and slight shrinkage occurs. Typical bisphenol–curable stocks undergo a 0.3 % mass loss on press curing and a further 1.2 % loss on postcuring [115], [116]. Postcuring is believed to complete the vulcanization and deactivate remaining intermediates. In this view, improved compression-set resistance on postcuring is seen as reduction of the formation of a second network under compression, with more complete recovery to the uncompressed dimensions. The conditions for a postcure cycle are established rather arbitrarily, because each elastomer-curing system has a point at which improvement of properties on heating a vulcanizate in air gives optimum properties, beyond which further heating or heating at a higher temperature affects physical properties undesirably with the onset of heat aging.

Vulcanization Chemistry. The chemical reactions that result in formation of networks in VDF–HFP-based fluoroelastomers compounded with bisphenols or other polyhydroxy aromatics, quaternary phosphonium or ammonium salts, and inorganic bases are believed to involve dehydrofluorination of HFP–VDF–HFP or HFP–VDF–TFE sites. The resulting double bonds are susceptible to nucleophilic substitution because of their electron-deficient character. Thus, a quaternary phosphonium or ammonium phenolate displaces a vinylic or allylic fluorine and forms the first attachment of an aromatic bisether cross-link [101], [117], [118].

Peroxide-initiated cross-linking of bromine-containing fluoroelastomers in the presence of radical traps such as triallyl isocyanurate is believed to proceed by radical-initiated polymerization of the radical trap to form a network that retains a substantial fraction of the allyl functions. When further polymerization of these functions becomes slow, the propagating radicals abstract bromine atoms from the fluoroelastomer; the resulting fluorocarbon radicals attack intact allylic double bonds. The driving force for this reaction is the addition of an electron-deficient free radical to an electron-rich double bond. Propagation reactions may involve redistribution of the free-radical intermediates from fluoroelastomer radical addition to a double bond of the partially polymerized radical trap [101], [119].

3.2.4. Uses

Vinylidene fluoride based elastomers are used widely in vehicle construction because of their excellent resistance to heat and oil. Important fluoroelastomer parts are engine oil seals of both the rotating and reciprocating types, drive-train seals, and fuel-handling components such as gaskets, O-rings, valve seals, and hoses. Other applications are hydraulic and pneumatic seals, hose and seals for chemical industry, flue-duct expansion joints for power plants and pollution control equipment, and fuser rolls for copying

machines. The aircraft industry uses more fluorosilicone than fluorocarbon elastomers because of the extreme low-temperature requirements of high-altitude flight [120].

3.3. Elastomers Based on Tetrafluoroethylene–Perfluoro(Methyl Vinyl Ether) Copolymers

Despite the vast improvement that VDF-based elastomers offered over conventional hydrocarbon elastomers in thermooxidative stability and oil resistance, even more stable elastomers were required for critical industrial and military applications. In response to this need, perfluorinated materials were developed at Du Pont in the 1960s. The goal was an elastomer with the inertness and solubility characteristics of PTFE or poly(TFE−HFP).

To create such a stable elastomer, a comonomer was required that would interrupt TFE crystallinity and impart good low-temperature properties. At this time, the epoxidation of HFP was developed and the resulting hexafluoropropylene oxide could be isomerized to perfluoro(methyl vinyl ether) (PMVE) (→ Fluorine Compounds, Organic, Chap. 6.2.).

Copolymerization of PMVE with TFE gave an elastomer [*26425-79-6*] whose thermal, oxidative, and chemical stability before cross-linking approached that of perfluorocarbon plastics [121]. However, the inertness of this base elastomer and the absence of cure sites prevented cross-linking, and most of the effort to develop a practical elastomer went into cure site monomers [122–127]. Several types of curing systems were developed, and articles made from them were commercialized by Du Pont in the mid-1970s under the Kalrez Perfluorocarbon Elastomer Part trade name.

3.3.1. Production

Copolymerization of TFE–PMVE and cure-site monomers is conducted in an aqueous emulsion like that used with VDF–HFP-based systems (see 3.2.1). Polymerization rates in continuous reactors are about one-tenth those of VDF–HFP-based systems at temperatures that give useful molecular mass. Initiation is effected by thermal dissociation of persulfate or by redox couples such as persulfate–sulfite. An important difference between the polymerization of VDF–HFP and TFE–PMVE is that the latter require a surfactant. Hydrocarbon-based surfactants cannot be used because of chain-transfer reactions with the highly reactive perfluorocarbon chain radicals; salts of C_8-C_{12} perfluorocarbon acids are satisfactory.

The polymer latex is coagulated by addition of polyvalent metal salt solutions. The polymer crumb is filtered or centrifuged and washed to remove coagulant, initiator, and surfactant and then dried [125].

3.3.2. Properties

Heat Resistance. The mass loss of a TFE−PMVE copolymer in air over 7 d at 316 °C is 6.5 %; an uncured terpolymer that contains the proprietary perfluorophenoxy ether-based cure-site monomer loses 12 % under the same conditions [125]. This typical behavior is to be expected in a perfluoroelastomer because the cure site has a more complex structure than the backbone and is more prone to degradation under these extreme conditions. Degradation of the cure site would also be expected to lead to some local degradation of the main chain.

Cured perfluoroelastomer specimens are also exceptionally stable and are differentiated by the stability of their cross-links. A perfluoroelastomer with a perfluorocarbon nitrile group as cure site retains physical properties best under extreme heat conditions. The triazine cross-links that are believed to form by trimerization of the nitrile functions are sufficiently stable to prevent any change from the original postcured properties with respect to 100 % modulus, tensile strength, and elongation at break over 18 d at 288 °C in air. Even at 316 °C, useful properties are maintained: 100 % modulus is reduced by less than 20 % and tensile strength by less than 40 %; elongation at break is unchanged.

Although perfluoroelastomers cross-linked through the perfluorophenoxy group are less stable to heat, they are still far more stable than hydrofluoroelastomers: after 20 d at 288 °C in air, 100 % modulus is reduced by less than 25 % and tensile strength by less than 15 %; elongation at break is increased 120 %.

Fluid and Chemical Resistance. Uncured TFE−PMVE-based perfluoroelastomers are insoluble in all solvents except certain perfluorocarbons and chlorofluorocarbons. Dilute solutions can be prepared in Freon 113 or 2,2,3-trichloroheptafluorobutane containing 2 – 3 % of a highly polar solvent such as methanol or tetrahydrofuran.

In 10 d at 25 °C, mass increases 61 % in diethylamine, 90 % in fuming nitric acid, and 41 % in Skydrol 500-B, a phosphoric ester based hydraulic fluid; Freon 113 swells the polymer, with a 40 % mass gain [125], [126]. Permeability values for a 0.127 mm calendered film at 24 °C, in g mm^{-1} h^{-1} cm^{-2} are as follows:

Benzene	1.5
Carbon tetrachloride	1.3
Ethyl acetate	1.7
Methanol	0.3
Diethylamine	0.5
Isooctane–toluene 1 : 1 (Reference fuel C)	1.1
Water	< 1.3

The swelling resistance of cured carbon black-containing TFE−PMVE−X perfluoroelastomers in various liquids at elevated temperature is shown in Table 17. Large differences exist between the triazine, K_2−AF, and peroxide curing systems. The triazine cure refers to trimerization of perfluorocarbon nitrile groups. The K_2−AF cure refers to the dipotassium salt of bisphenol AF that is used to cross-link polymers with perfluorophenoxy groups. The peroxide cure indicates free-radical cross-linkage of a bromine-containing perfluoroelastomer.

Typical physical properties of a K_2−AF-cured vulcanizate loaded with carbon black follow [126]:

100 % modulus	9 MPa
Tensile strength	16 MPa
Elongation at break	160 %
Hardness, Shore A	75
Compression set B (O-rings)	
70 h at 121 °C	23 %
70 h at 288 °C	45 %
Clash–Berg torsional-stiffness temperature (66.9 MPa)	−2 °C
Brittle point	−38 °C
Retraction temperature	
TR-10	−1 °C
TR-50	+8 °C
Relative density	2.05

3.3.3. Processing and Uses

Perfluoroelastomers based on TFE−PMVE are difficult to process because of the stiffness of the fully fluorinated chains. Since the polymer is also difficult to cross-link and expensive to produce, Du Pont commercialized these materials in the form of finished articles under the trade name Kalrez Perfluorocarbon Elastomer Parts. A substantial market was found for O-rings, flat and lathe-cut gaskets, rotating and reciprocating shaft seals, and diaphragms. Other products include coated fabrics, hose linings, tubing, industrial gloves, and extruded articles such as autoclave and oven seals. The high cost of these products is justified in applications where no other material is equally resistant to oxidative, thermal, fluid, and chemical exposure. They are used in the manufacturing, aerospace, and automobile industries.

3.4. Elastomers Based on Tetrafluoroethylene–Propylene Copolymers

Du Pont [131] and Asahi Glass [132–134] established independently in the 1960s that TFE and propene (P) undergo a nearly alternating polymerization. The resultant TFE−P fluoroelastomer [*27029-05-6*] exhibits very good thermal and chemical resistance, but has a high glass transition temperature (−2 °C) despite its low fluorine content (54 %). Although resistance to swelling by aromatic hydrocarbons is inadequate, these elastomers offer excellent resistance to certain polar solvents. An unusual property of TFE−P fluoroelastomers is their exceptional resistance to dehydrofluorination by organic bases. As a result, they are cured by peroxide-radical trap systems [135], unless a specific cure site is present [136], [137].

Asahi Glass introduced TFE−P polymers in the mid-1970s under the Aflas trade name. In 1987, TFE−P-based fluoroelastomers represented only a small fraction of the total fluorocarbon elastomer market.

Table 17. Chemical and fluid resistance of perfluoroelastomers [128–130]

Liquid	Temperature, °C	Time, h	Swell of cured elastomer, %		
			Triazine	K_2-AF	Peroxide
Nitric acid	85	70	3	8	9
Acetic acid	100	70	3	32	16
Aniline	100	166	5	2	6
Butyraldehyde	70	70	13	10	14
Toluene	100	70	7	7	7
Skydrol 500-B	125	70	9	5	6
Methyl ethyl ketone	70	70	6	4	4
Water	225	70	27	60	7

3.4.1. Production

Tetrafluoroethylene–propylene elastomers are prepared in aqueous emulsion with a perfluorocarbon surfactant. Batch copolymerization at 70 – 80 °C, using a conventional ammonium persulfate–sodium sulfite redox catalyst, produces elastomers of relatively low molecular mass ($\bar{M}_w$=70 000) because of chain transfer. Polymerization below 60 °C to increase molecular mass requires a change in initiator because the persulfate–sulfite couple is too unreactive at such temperatures. To maintain a reasonable polymerization rate, more active redox initiators were developed [134]. With these catalysts, combinations of ammonium persulfate, ferrous sulfate, ethylenediaminetetraacetic acid, and sodium hydroxymethanesulfinate, efficient batch polymerization to a $\bar{M}_w$ of 15×10^4 can be carried out in the 25 – 35 °C range. The emulsion is buffered with disodium hydrogen phosphate and sodium hydroxide to maintain the pH between 5.5 and 10.

The polymer latex is coagulated by addition of solutions of polyvalent salts, and the coagulated crumb is washed and dried.

3.4.2. Properties

Typical properties of a TFE−P elastomer vulcanized by a peroxide–radical trap curing system (press-cured at 160 °C for 30 min, postcured at 200 °C for 2 h) are as follows [134]:

Raw polymer	
Relative density	1.55
Mooney viscosity (ML-10, 100 °C)	85
Appearance	dark brown
Formulation	
Poly(TFE−P)	100 phr
α,α'-Bis(*t*-butylperoxy)diisopropylbenzene	2 phr
Triallylisocyanurate	3 phr
MT carbon black (N-908)	30 phr
Vulcanizate Properties	
Relative density	1.60
Tensile properties at 25 °C	
100 % modulus	3 MPa
Tensile strength	20 MPa
Elongation at break	300 %
Compression set at 200 °C	
1 d	40 %
30 d	65 %
Hardness, Durometer A	72
Brittle point	−40 °C
Retraction temperature (TR-10)	3 °C
Volume increase after immersion	
95 % H_2SO_4, 100 °C, 3 d	4.4 %
Water, 150 °C, 3 d	8.7 %
Steam, 160 °C, 3 d	4.6 %
Fuel Oil B, 25 °C, 7 d	59 %
Benzene, 25 °C, 7 d	40 %
Methanol, 25 °C, 7 d	0.2 %
Ethyl acetate, 25 °C, 7 d	88 %

3.4.3. Processing

Tetrafluoroethylene–propylene fluoroelastomers are formulated as follows: Dialkyl peroxides are used with radical traps such as polyallyl or polyvinyl compounds or *N,N′-m*-phenylenedimaleimide. An inorganic acid acceptor such as calcium hydroxide or magnesium oxide is also present. Fillers such as silicas can be used, but carbon blacks are usually chosen for reinforcement [134].

Tetrafluoroethylene–propylene elastomers process less smoothly on conventional rubber processing equipment than VDF–HFP-based fluoroelastomers. Processing aids such as carnauba wax or sodium stearate are widely employed. Similarly, longer press-cure cycles are used to develop optimum properties: the press-cured vulcanizates are usually postcured at 200 °C for 16 h [138], [139].

3.4.4. Uses

The TFE–P fluoroelastomers are used where high temperatures and destructive media are encountered. Applications are similar to those described for VDF–HFP-based polymers (Section 3.2.4), but the choice may depend on specific requirements. Thus TFE–P is recommended for exposure to strong organic bases and certain highly polar solvents, but not for maximum oil resistance and low-temperature properties.

4. Toxicology and Occupational Health

All commerical fluoropolymers today are low in toxicity and safe under normal conditions. They are physiologically inert and some have been approved by the FDA for use in contact with food or for human implants. Incineration of fluoropolymers should be avoided because the combustion products include hydrogen fluoride, a toxic and corrosive gas. Certain processing hazards are discussed separately for fluoroplastics and fluoroelastomers.

4.1. Fluoroplastics

Polytetrafluoroethylene resins are subjected to prolonged heating at 380 °C during sintering. Since a small quantity of toxic fumes can be emitted during this process, adequate ventilation should be provided to prevent inhalation of the fumes, which can cause a condition known as polymer fume fever. This temporary flulike disorder occurs several hours after exposure and lasts for 36 – 48 h. The effect is not cumulative. It is often caused by smoking tobacco contaminated with PTFE powder. Therefore, smoking should be forbidden in areas where PTFE is processed. Safe handling practice must be observed during processing [34]. Enormous quantities of PTFE resins have been manufactured, processed, and used without causing any known cases of serious illness or death.

The same precautions should be followed with all TFE-containing polymers. In the extrusion or molding of TFE copolymers, the resin is heated above 300 °C (to 425 °C in the case of PFA resins). Exhaust hoods should be used over the die and feed hopper to remove any toxic fumes that may be evolved.

The main hazard associated with the processing of PVDF, ECTFE, and PVF resins is the evolution of hydrogen fluoride; this is prevented by avoiding overheating. Exhaust hoods should be used over the feed and die sections of the extruder or molding machine to remove hydrogen fluoride.

4.2. Fluoroelastomers

Fluorocarbon elastomers are nontoxic and nonirritating when handled in accordance with manufacturers' recommendations. Detailed literature on safety is available from the manufacturers; the following general principles should be observed: (1) adequate ventilation of compounding, extrusion, curing, and postcuring areas should be provided; (2) dispersion of finely divided active metals or high concentrations of active dehydrofluorinating agents (e.g., aliphatic amines and combinations of phase-transfer catalysts with metal oxides or hydroxides) should be avoided; (3) fluoroelastomers should not be heated to or above their decomposition temperature; and (4) incineration should not be used as a waste disposal method because of the attendant evolution of hydrogen fluoride.

Certain compounding ingredients may pose specific hazards, and manufacturers' or suppliers' recommendations should be followed.

Certain fluoroelastomers have been approved for contact with foods under the Code of Federal Regulations, 21, Food and Drugs, Part 177.2600.

5. Economic Aspects

Fluoroplastics. Worldwide production capacity in 1987 for all fluoroplastics was ca. 45 000 t. Selling prices ranged from ca. $9 to 44/kg. Du Pont is the world's leading producer, with plants in Europe, Japan, and the United States. Other major producers include Asahi Glass (Japan), Ausimont (Italy), Daikin Kogyo (Japan), Dynamit Nobel (FRG), Hoechst (FRG), ICI (UK), Kureha Chemical Co. (Japan), 3M (USA), Pennwalt Corp. (USA), and Solvay & Cie. (Belgium).

Fluoroelastomers. Worldwide annual consumption of fluorocarbon elastomers was estimated to be 5000 t in 1987. Prices for non-PMVE fluorocarbon elastomers ranged from ca. $33 to 45/kg. Fluoroelastomers are produced by Du Pont (Deepwater, USA) and Dordrecht (Netherlands); by 3M (Decatur, USA) and Zwindrecht (Belgium); by Montefluos (Linate, Italy); by Daikin Kogyo (Osaka, Japan); and by Asahi Glass (Chiba, Japan.)

1. Introduction

Fluorosulfuric acid [*7789-21-1*], HSO_3F, M_r 100.07, is a colorless to pale yellow liquid of stinging odor, which fumes readily in moist air. The halogen is more firmly bonded than that of chlorosulfuric acid so that fluorosulfuric acid is hydrolyzed more slowly than chlorosulfuric acid. Under favorable conditions, it is even possible to prepare salts in aqueous solution [3].

Fluorosulfuric acid was first mentioned in 1892 [4], [5]. The method of preparation, which is the one still used, from hydrogen fluoride and sulfur trioxide, was also described. Fluorinations using HSO_3F and catalysis of alkylations and cyclization by HSO_3F have been known for a long time. Industrial processes include the production of boron trifluoride [6] and the polymerization of tetrahydrofuran [7]. The chemical polishing of lead crystal glass with the acid was described in the 1960s [8].

The composition of commercial fluorosulfuric acid (wt %) is $\geq 99.0\,\%$ HSO_3F, $\leq 1.0\,\%$ H_2SO_4, $\leq 0.6\,\%$ free SO_3, $\leq 0.1\,\%$ SO_2, and $\leq 0.003\,\%$ Fe. The physical properties are listed in Table 1.

Table 1. Physical properties of fluorosulfuric acid

Melting point *mp*, °C	− 88.98
Boiling point *bp*, °C	
at 101.3 kPa	162.7
16.0 kPa	110
2.5 kPa	77
Density ϱ, g/cm^3	
at 18 °C	1.740
at 25 °C	1.725
Vapor pressure p at 25 °C, Pa	330
Viscosity η at 25 °C, mPa s	1.56
Heat of formation ΔH_f (liquid), kJ/mol	792.45

The salts and derivatives of fluorosulfuric acid have had no industrial importance.

2. Preparation

Hydrogen fluoride and sulfur trioxide are introduced, with stirring, into fluorosulfuric acid, which serves as a solvent for the reaction. The fluorosulfuric acid is pumped through a cooler to keep the temperature in the reactor constant at $< 100\,°C$ (Fig. 1).

Figure 1. Preparation of HSO_3F
a) Cooler; b) Level control; c) Pump; d) Conductometer

Uses. In *inorganic chemistry,* fluorosulfuric acid is suitable for fluorination reactions, which proceed more gently than fluorination with hydrofluoric acid. Examples:

$SiO_2 \longrightarrow SiF_4$ [9]
$H_3BO_3 \longrightarrow BF_3$ [6]

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a11_431

$NO_x \longrightarrow FSO_3NO_x$
$As_2O_3 \longrightarrow AsF_3$ [10]
$KClO_4 \longrightarrow ClO_3F$ [11]

The last product, ClO_3F, is a reagent for the fluorination of organic compounds.

Fluorosulfuric acid is used to restore baths for chemically polishing lead glass to their initial strength. The polishing baths, as a rule, consist of 60 – 70 wt % H_2SO_4, 2 – 6 wt % HF, with the remainder water. During the polishing process, the glass surface is partially dissolved, which can be represented by the following equations:

$$PbO + H_2SO_4 \longrightarrow PbSO_4 + H_2O$$
$$SiO_2 + 6\,HF \longrightarrow H_2SiF_6 + 2\,H_2O$$

The acids consumed are replaced by fluorosulfuric acid, which is rapidly hydrolyzed in the strong acid, consuming some of the water formed during glass polishing:

$$HSO_3F + H_2O \longrightarrow H_2SO_4 + HF$$

In this way, the fluorosulfuric acid covers ca. 28 % of the total hydrofluoric acid requirement. When fluorosulfuric acid is added, 1.5 – 2 kg of waste acid is produced per kilogram of glass removed, but if a mixture of 96 % sulfuric acid and hydrofluoric acid are added to regenerate the polishing acid, 2.5 – 4.5 kg of waste acid is produced per kilogram of glass removed [12].

In organic chemistry, fluorosulfuric acid can be used as a catalyst for the alkylation of olefins, polymerizations, and isomerizations. The reactive alkyl ester of fluorosulfuric acid is evidently responsible for the catalytic activity [13]. Examples of alkylations:

Alkylation of olefins with ca. 13 % fluorosulfuric acid as catalyst [14]

Alkylation of isoparaffins with an olefin [15]

Formation of high-octane fuels from low-octane hydrocarbons by reaction with isobutane in the presence of fluorosulfuric acid and SbF_5 (magic acid) [16]

Formation of alkylated aromatics from aromatics (e.g., benzene) and ethylene with BF_3 and fluorosulfuric acid at ca. 10 kPa and room temperature [17]

Alkylation of phenol to *o*- and *p-tert*-butylphenol [18]

Examples of polymerization and isomerization reactions:

Polymerization of tetrahydrofuran [7]
Polymerization of ethylene with fluorosulfuric acid and BF_3 as catalyst to give long-chain unsaturated hydrocarbons [19]
Polymerization of trioxane to polyoxymethylene with fluorosulfuric acid and SbF_5 (magic acid) [20]
Isomerization of C_7 hydrocarbons to branched products [21]
Isomerization of pentene to isopentene [22]
Isomerization of methylpentene with sulfuric acid and fluorosulfuric acid to give isomethylpentene [23]

In the preparation of naphthol from naphthalene by catalytic hydroxylation with hydrogen peroxide, α-naphthol is formed selectively in classical acid systems, such as hydrogen fluoride, whereas the use of fluorosulfuric acid and SbF_5 as the catalyst produces β-naphthol with an isomeric purity between 92 and 98 % [24].

Fluorosulfuric acid has been proposed to remove hydrogen fluoride from elemental fluorine [25]. The customary purification with NaF, which forms slightly soluble $NaHF_2$, has the disadvantage that $NaHF_2$ is difficult to decompose. In contrast, hydrogen fluoride absorbed in fluorosulfuric acid can simply be distilled off.

3. Analysis

The principal impurities in fluorosulfuric acid can be determined by the following methods [2]:

1)	HF	A known excess of SO_3 is added. The free SO_3 is then back-titrated with water, with conductometric determination of the end point.
2)	SO_3	Direct titration with water, as in Method 1. Free SO_3 can be detected by the blue color upon addition of sulfur.
3)	H_2SO_4	The specific electrical conductivity at the end point of the titration in Method 1 or 2 is a function of the resulting sulfuric acid content of the fluorosulfuric acid. This allows determination of the sulfuric acid content if the quantity of sulfuric acid formed during titration is subtracted from the total.

Fluorosulfuric acid can be identified by infrared spectrometry [2], [26].

4. Safety Measures and Regulations.

Fluorosulfuric acid and its vapors are corrosive to eyes, mucus membranes, and skin. Reaction with water (humid air, perspiration, etc.) produces sulfuric and hydrofluoric acids by hydrolysis. As a result, contact with fluorosulfuric acid, especially if the eyes are involved, can result in injury from hydrofluoric acid, with all the accompanying complications: hydrofluoric acid also penetrates the skin, destroys the underlying tissues, and causes acute disruption of metabolism by binding Ca^{2+} and Mg^{2+} and inhibiting essential enzymes (Toxicology in → Fluorine Compounds, Inorganic).

Therefore, great care should always be taken in the handling of fluorosulfuric acid, and the safety regulations should always be followed exactly. In the Federal Republic of Germany, for example, the general rules of the Berufsgenossenschaft der chemischen Industrie, an association like the U.S. OSHA, to avoid accidents (Data Sheet M005) [27] should be observed.

In case of exposure to fluorosulfuric acid, all parts of the body that were exposed should be washed thoroughly with water and treated with a calcium gluconate solution (> 1 wt %), and the patient brought as quickly as possibly to a physician. (The physician should be informed and provided with Data Sheet M005.)

If fluorosulfuric acid is swallowed, milk of magnesia (20 wt % MgO in water) or calcium gluconate solution should be administered immediately. In no case should vomiting be induced.

Plant employees should wear appropriate protective clothing when working with fluorosulfuric acid, e.g.,

Breathing apparatus	air filter (type ABEK) if the MAK is exceeded
Gloves	fabrication out of Viton
Eye protection	protective glasses, face shield, possibly a protective helmet of Viton

If these devices are not adequate, then a complete protective Viton suit, providing protection for the head, face, and neck and including jacket and pants or overalls, and PVC boots must be worn.

Upon contact with organic material, in extreme cases, fluorosulfuric acid can induce ignition. Any spilled fluorosulfuric acid should be diluted with a large amount of water (the reaction with water is violent, and fogs can form). If spilled fluorosulfuric acid is foggy, surround the acid puddles with barriers of dry sand and cover with Diakon LG 156 Clear 001 (ICI) or Sedipur NF 102 (BASF) to avoid fogs. Small amounts of fluorosulfuric acid are best destroyed by mixing with tenfold the amount of cold, concentrated (96 %, better 98 %) sulfuric acid. This mixture is then treated slowly with ice until it is sufficiently dilute, and is then neutralized with lime.

In the Federal Republic of Germany, with respect to identification and handling, fluorosulfuric acid is subject to the *Decree on Hazardous Substances* of October 26, 1993.

The procedures necessary for the safe handling of fluorosulfuric acid at the Bayer works at Leverkusen, Federal Republic of Germany, have led the German chemical industry to expand the identification prescribed in the *Decree on Hazardous Substances* of October 26, 1993 by the symbols in Table 2.

Table 2. R and S phrases for fluorosulfuric acid

Symbol	Meaning
R 20	injurious to health when inhaled
S 26	upon contact with the eyes, flush thoroughly with water and consult a physician
S 45	if feeling unwell, obtain medical advice (if possible, showing container label)

The following safety regulations apply in the USA: Data Sheets SD20 and SD25 [28].

5. Transport, Storage, and Filling.

Samples of fluorosulfuric acid are supplied in Teflon or aluminum bottles. When opening the bottles, the following safety precautions should be taken: Viton gloves, safety glasses, face shield, and if necessary, appropriate clothing.

The following type of drum is permitted: air-tight closed steel or aluminum rolling hoop drums up to 220 L in capacity. Self-supporting plastic drums are not permitted. All drums must be protected against the sun and, above all, against heat. They should be opened once a week to dissipate any pressure that may have developed.

Fluorosulfuric acid may be shipped in road tankers, tank wagons, or tank containers. The tanks must be designed for a pressure of at least 1 kPa (= 10 bar) and tested at a pressure of at least 0.4 kPa (= 4 bar). For tanks in which fluorosulfuric acid is stored or transported a bottom outlet is not permitted. During unloading, in the Federal Republic of Germany, for example, Data Sheet T015 [29] must be complied with. In the transportation and loading data sheets fluorosulfuric acid is often called fluorosulfonic acid.

The following regulations apply for transport (as of 1995):

IMDG (international sea transport)	Class 8 UN No. 1777, Packing Group I
ADNR (European waterways)	Class 8 item 8 A
IATA-DGR (international air transport)	Class 8 UN No. 1777, Packing group I
RID/ADR (European railway and roads)	Class 8 item 8 A

1. Introduction

Foamed plastics are materials that have cells distributed throughout their entire mass. A cell is a small void formed during the manufacture of the foam; it is enclosed partly or completely by *cell walls* or *struts*. In contrast to an open cell, a closed cell is totally surrounded by its walls and, therefore, is not interconnected with other cells via the gas phase.

The apparent density of a foamed plastic depends on the fraction of the total volume occupied by the polymer phase that forms the skeleton; it is always lower than the density of the skeletal substance [12].

Structural foams consist of a light, closed-cell core that is sandwiched between solid integral skins. *Syntactic foamed plastics* are gas-filled polymers that are not, however, foamed. They contain completely closed cells that are formed by hollow spheres distributed in the polymer matrix (see page 22).

The constituents of the polymer skeleton can be produced by polymerization, polyaddition, or polycondensation.

History. The first foamed polymers were produced in the 1920s from rubber (Dunlop). These were followed in the 1930s by foamed plastics from urea resin (BASF), flexible poly(vinyl chloride) (I.G. Farben), and polyurethane (Bayer). Polyethylene foams (Du Pont), extruded polystyrene foams (Dow), rigid poly(vinyl chloride) foams (Lonza), and the first phenolic resin foam (Dynamit Nobel) were developed during World War II. Foams from polystyrene beads (BASF), epoxy resins (Shell), and silicones (Dow Corning) were announced in the late 1940s and early 1950s. In the 1960s, polyamide (BASF), polycarbonate (General Electric), polysulfone (Pechiney-Saint-Gobain, ICI), polyimide (Du Pont), and polymethacrylimide (Röhm) foams were described. Poly(phenylene oxide) (General Electric), and melamine resin (BASF) foams have been known since the 1970s.

2. Production (→ Plastics, Processing)

Production processes for individual foams are described in Chapter 4. Only a brief overview is given here.

2.1. Principles

The three key starting materials for a foam are polymer, blowing agent, and additives.

In the manufacture of *thermoplastic foams,* the starting material is generally an existing polymer. Foams are produced in both continuous and batchwise processes which frequently involve an extrusion step. Thus, boards or films as well as profiled and shaped parts with various apparent densities can be produced (e.g., Section 4.2.2).

Foamed thermoplastic beads are fused with steam to form a variety of shaped parts, including blocks (Sections 4.1.1 and 4.2.1).

In the manufacture of *thermoset foams,* the macromolecules are cross-linked during the foaming process. The foams are produced in various ways. The pourable charge is distributed on a conveyor belt where the mixture foams and hardens continuously (Sections 4.4 and 4.6). The resulting paste can also be poured into block molds (Section 4.4) or other cavities where the reaction is completed (Sections 4.7 and 4.8). Whipping (Section 4.5) and spraying (Sections 4.4 and 4.8) processes may also be used.

2.2. Blowing Agents

In almost all foamed plastics, the volume fraction of the gas phase (a function of density) is far greater than that of the skeletal substance. Thus, for example, at an apparent density of 10 kg/m^3, the gas phase accounts for ca. 99 % of the volume. The gas phase is produced by using a blowing agent.

Physical blowing agents may be compressed gases (air, nitrogen) or low-boiling hydrocarbon or chlorofluorocarbon (CFC) liquids, e.g., butane, pentane, trichlorofluoromethane (CFC 11). They do not leave undesirable decomposition products.

In the oldest method, originally developed for rubber, air is whipped mechanically into the latex [13]. The resulting froth is fixed by cross-linking. This process is commonly used for urea–formaldehyde resin foams (Section 4.5) and flexible poly(vinyl chloride) (PVC) foams (Section 4.3.2).

In an alternative method, compressed nitrogen is dissolved in a polymer melt. The cellular structure is then obtained by reducing the pressure. Examples are the batchwise production of cross-linked polyethylene foam (Section 4.1.1) and injection molding.

Incorporation of the blowing agent pentane [*109-66-0*] into polystyrene beads (Section 4.2.1) renders them heat-expandable.

Low-boiling chloro- and chlorofluorocarbons are incorporated into polyethylene (Section 4.1.1) or polystyrene melts (Section 4.2.2) in an extruder. Trichlorofluoromethane [*75-69-4*] (CFC 11) and 1,2-dichloro-11,22-tetrafluoroethane [*76-14-2*] (CFC 114) are used as blowing agents for polyethylene. Methyl chloride [*74-87-3*], ethyl chloride [*75-00-3*], and trichlorofluoromethane [*75-69-4*] (CFC 11) are used for expandable polystyrene. The blowing agents evaporate and the polymer expands. Cooling increases the viscosity and sets the skeleton of the foam.

Thermoset foams (Sections 4.4 and 4.6) are also produced with low-boiling liquid blowing agents which are activated by the heat of the cross-linking reaction or by externally supplied energy.

The choice of blowing agent is based on a knowledge of physical and chemical properties [14].

Chemical blowing agents are solids which decompose at elevated temperature with the formation of gas. For optimum action, they must be distributed very uniformly in the substrate. Their decomposition temperature must be suitable for the processing temperature of the polymer. Numerous organic, nitrogen-containing substances with decomposition temperatures of 100 – 250 °C [15], [16] or higher [17] are known (e.g., azo compounds, nitroso compounds, and hydrazides). The most frequently used compound is azodicarbonamide [*123-77-3*] which splits off nitrogen and carbon monoxide at about 200 °C. The decomposition temperature can be lowered by various additives such as zinc oxide [18].

The compounds, which contain polymers and blowing agents, are then subjected to extrusion processing.

If chemical blowing agents are used, thermoplastic foam injection molding (TFI) and thermoplastic foam extrusion (TFE) are usually employed to yield heavy, foamed plastics known as *structural* (*integral*) *foams* (Section 4.2.3). The injection mold (TFI) or the die (TFE) is cooled so that the foam collapses at the wall of the mold or die and forms a compact surface layer. The compacted surface has nearly the same density as the polymer matrix, whereas the internal layers are foamed.

Inorganic blowing agents, such as carbonates, are of minor importance. A mixture of sodium bicarbonate [*144-55-8*] and citric acid [*77-22-9*] serves as an additional, nucleating blowing agent in combination with pentane (Section 4.2.2). Sodium borohydride [*16940-66-2*], which splits off hydrogen in the presence of water and is adsorbed on fumed silica, has been reported to be an effective blowing agent [19].

Blowing agents can also be formed as reaction side products. For example, in certain polyurethane foams and in thermoset-modified PVC foams, carbon dioxide is formed from isocyanate and water (Section 4.3.1). Polyimide foam is blown by the alcohol (usually ethanol) formed in the imidization reaction (Section 4.9).

2.3. Additives

Nucleating agents are important additives in foam manufacture, especially in physically blown, thermoplastic foams. They are finely dispersed, often silicate-like solids but they may also be waxlike. They act as boiling chips in the polymer melt which is supersaturated with dissolved blowing gas.

Minute, nucleating gas bubbles, called hot spots, are also formed during the initial decomposition of chemical blowing agents [20]. Gaseous side products of the reaction act in the same manner.

Surfactants are required in thermosetting plastics to emulsify the liquid blowing agent. They reduce interfacial tension and thus facilitate nucleation. The surfactant also stabilizes the foam during expansion until the foam is set by the simultaneous hardening process.

Other additives include dyes, inert or reinforcing fillers and fireproofing agents. Antioxidants and UV stabilizers are sometimes needed.

Figure 1. Compressive strength and apparent density of foamed plastics
∗ Also include flexible foams.
Abbreviations are defined in the abbreviation list at the beginning of this article.

3. Properties

The properties of foamed plastics are determined by their polymer substrate, apparent density, and morphology.

All three parameters, but especially apparent density, affect mechanical behavior. Resistance to elevated temperature and to chemical agents, as well as fire behavior, are primarily determined by the polymer. Morphology is responsible for the acoustical and thermal insulating properties. Both morphology and polymer substrate determine the water balance (water absorption, diffusion of water vapor).

Compressive Strength. One the basis of their compressive strengths determined in a compression test at 10 % deformation (DIN 53 421, ISO 844), foamed plastics are classified as *rigid* (> 0.08 MPa), *semirigid* (0.015 – 0.08 MPa) or *flexible* (< 0.015 MPa) [12]. The measured compressive strength depends primarily on the apparent density of the foamed plastic but also on the modulus of elasticity of the polymer [21].

Figure 1 provides an overview of the ranges of apparent density and compressive strength for individual foams. A linear relationship exists between the logarithms of the compressive strength and of the apparent density for all rigid plastic foams [15, p. 411], [22]. Polyethylene foams lie parallel to the scatter band; flexible plastic foams and some semirigid are outside it.

Figure 2. Scanning electron micrographs of (A) a closed-cell, extruded polystyrene foam and (B) an open-cell melamine–formaldehyde foam

Cell Structure. Rigid and semirigid plastic foams generally have *closed cells* which do not interconnect via the gas phase. They can, therefore, also contain gases other than air, e.g., fluorocarbons. Flexible foams, on the other hand, are usually *open-celled* and filled with air. Exceptions to this rule are, however, found. Figure 2 shows scanning electron micrographs of a closed-cell (A) and an open-cell (B) plastic foam.

The *cell size* of most plastic foams is 0.05 – 1 mm. Thermoset-modified PVC foams, and noncross-linked, extruded polyethylene and poly(methyl methacrylate) foams have cell sizes > 1 mm. Foams with smaller cells usually exhibit better mechanical behavior.

If the cells are oriented, e.g., stretched in the rising direction of the foam, the mechanical properties are no longer isotropic.

The thickness of the cell wall of closed-cell foams, the strut thickness of open-cell foams, and the cell size affect the radiant fraction of thermal conductivity. Each material has an optimum value [23], [24].

Figure 3. Thermal conductivity of foamed plastics as a function of apparent density
Values were measured at 10 °C according to DIN 52 612, ISO-DIS 8302, ASTM C 177. The gases used to fill the foams, air or a chlorofluorocarbon (CFC), are indicated in parentheses. Dashed lines indicate that values vary widely. EPS = expandable polystyrene; MF = melamine–formaldehyde resin; PE = polyethylene; PF = phenol–formaldehyde resin; PUR = polyurethane; UF = urea–formaldehyde resin; XPS = extruded polystyrene

Thermal Insulation. The thermal insulation of a foamed plastic depends primarily on the thermal conductivity of the filling gas, followed by the apparent density and then morphology. Foams filled with heavy chlorofluorocarbon gases, therefore, have better thermal insulation characteristics than air-filled foams. Figure 3 shows the density dependence of the thermal conductivities of several foams measured at 10 °C [25], [26].

Depending on prevailing conditions, open-cell products can absorb water and thus increase their thermal conductivity [27]. Since they are also open to diffusion, they must be provided with a barrier layer in some cases.

Sound Insulation. Open-cell foams are well suited for airborne sound insulation. Closed-cell products are useful for impact sound insulation, provided they have sufficient resilience [28]. Rigid foams are less suitable for acoustic applications.

Fire Behavior. Polymer-dependent properties (i.e., maximum long-term service temperature and oxygen index) are shown in Figure 4 for the individual foams discussed in Chapter 4. Thermoplastics differ from thermosets: when exposed to a flame, thermoplastic foams sinter above their softening range and melt, whereas thermosets form a carbon skeleton.

The oxygen index provides some indication of the flammability of a polymer. It measures the minimum oxygen concentration necessary to support combustion of the material [29]. Thus, higher values are better. The oxygen index of a foamed plastic may often be only slightly higher than that of the compact polymer, exceptions are urea–formaldehyde resins and poly(phenylene oxide).

Other important parameters for judging fire behavior are the smoke density and the toxicity of the combustion gases.

In compliance with the flammability requirements specified in guidelines for use in construction or transportation, some foams contain flame retardants. These are often halogen compounds, examples include chlorinated paraffins and hexabromocyclodecane for polyethylene and polystyrene, as well as boron trioxide for phenol—formaldehyde resins (cf. Chap. 5).

4. Specific Foamed Plastics

Polyurethane (PUR) foams are treated elsewhere (→ Polyurethanes). For a description of foamed

PVC coatings, see → Leather Imitates. Trade names of individual foams are listed in Table 1.

4.1. Polyolefin (PO) Foams

Polyolefin (PO) foams are manufactured by many producers in a variety of processes and are classified as low density (25 – 250 kg/m^3) or high density (250 – 700 kg/m^3). The market has expanded relative to other foamed plastics, especially in Japan.

Most polyolefin foams are made from low-density polyethylene [*9002-88-43*] (LDPE). Copolymers such as the more flexible ethylene–vinyl acetate [*24937-78-8*] (EVM) and, more rarely, high-density polyethylene [*9002-88-4*] (HDPE) are also found. Finally, foams may be produced from linear low-density polyethylene (LLDPE), a copolymer of ethylene and other olefins (1-butene to 1-octene) which is synthesized with a Ziegler catalyst. Polypropylene [*9003-07-0*] (PP), which is more resistant to heat deformation, stiffer, and tougher than polyethylene, was first processed into foamed sheets in the 1960s. Today, a polypropylene copolymer with a few percent ethylene is also utilized. For a detailed description of these polyolefins, see → Polyolefins. Trade names of polyolefin foams are listed in Table 1.

Fire Behavior. Like their starting materials, polyolefin foams are flammable. The smoke density is low. The combustion gases contain only carbon dioxide and, in case of oxygen deficiency, carbon monoxide.

4.1.1. Low-Density Polyolefin Foams (25 – 250 kg/m^3)

Boards, sheets, or profiled shapes are manufactured by continuous processes; boards are also

produced by batch processes. In addition, beads can be made continuously or batchwise.

Continuous Process for Non-Cross-Linked Foam. Non-cross-linked LDPE foam is produced by applying the technique used for polystyrene (Styrofoam, see Section 4.2.2) which involves the gassing of a polymer melt with low-boiling halogenated hydrocarbons in an extruder. The blowing agent evaporates as it emerges from the nozzle; the melt then cools and its viscosity increases [30]. A strand of closed-cell foam (cell size 0.5 – 1.5 mm) is formed, with a thickness of 80 mm and an apparent density of 30 kg/m^3. Thin sheets of foam up to 5 mm thick are produced in the same manner or via the film blowing process (→ Films,). An example of such a film is Ethafoam produced by Dow Chemical.

Cross-Linked Foams. As shown in Figure 5, LDPE melts in a very narrow range [31]. Cross-linked LDPE exhibits a less precipitous drop in viscosity with increasing temperature. Thus, a broader temperature range for processing is obtained; in addition, the foamed plastic has smaller cells.

Figure 5. Melt viscosity of low-density polyethylene (LDPE) as a function of temperature

Cross-linking is accomplished either chemically (e.g., with dicumyl peroxide [*80-43-3*]) or with beams of electrons at doses up to 20 Mrad.

The gel content (degree of cross-linking) should be ca. 30 – 60 % [32]. Occasionally, divinylbenzene [*1321-74-0*] [33] or oximes [34] are added to the peroxide. Polyolefins grafted with silanes can be cross-linked catalytically in contact with water [35], [36]. For polypropylene, cross-linking agents with higher decomposition temperatures are used, e.g., polysulfone azides [37].

Batch Process for Molded, Cross-Linked Foam. In the in-mold, molded foam (batch) method, preformed polyethylene boards containing peroxide cross-linking agents are placed in a mold and exposed to nitrogen at ca. 38 MPa

and 180 °C. After cooling and careful pressure reduction, the nitrogen remains dissolved in the melt. When heated to 100 – 130 °C, the partially cross-linked board foams to yield a foamed plastic. Its cells are very fine (0.1 mm), and its density is 24 – 70 kg/m^3 [38], [39]. This process is used by Bakelite Xylonite Ltd. to manufacture Plastazote.

∗ PE = polyethylene; PP = polypropylene; EVM = ethylene–vinyl acetate copolymer.

Instead of nitrogen, chemical blowing agents such as azodicarbonamide can also be used. The gel is removed from the mold rapidly while it is still hot and somewhat larger cells result.

Continuous Process for Cross-Linked Sheets. For the continuous manufacture of foam sheeting cross-linked with peroxides, the polyolefin (e.g., LDPE) is premixed carefully with up to 10 parts by weight of blowing agent (azodicarbonamide) and < 1 part by weight of cross-linking agent (dicumyl peroxide). The mixture is extruded to form a thin matrix which is then cross-linked by passing it through a heating tunnel at 180 – 230 °C. The sheet is finally foamed to a thickness of 4 – 20 mm and an apparent density of 25 – 250 kg/m^3. This process was developed by Furukawa and licensed to other companies (Bayer, Dynamit Nobel, Freudenberg) [32], [40], [41].

In a similar process, the matrix containing the blowing agent is cross-linked by irradiation with electrons. Subsequently, it is foamed in a

shaft by exposure to IR heaters and hot air at 200 – 250 °C (Fig. 6). Free expansion can also be carried out in a hot fluid bath. The depth of penetration of the electron beam limits the maximum thickness of the foamed sheet to 5 mm. Apparent densities are 30 – 200 kg/m^3. This process was developed by Sekisui and Alveo, it is used to produce Alveolit [32], [42], [43].

Figure 7. Production of expanded foam beads from polyolefin pellets
a) Pressure control valve; b) Polyolefin pellets; c) Pressure-resistant container; d) Water; e) Discharge valve; f) Orifice plate; g) Discharge tank; h) Expanded foam beads

Continuous Process Using Cross-Linked Beads. Strands of foam, produced by extruding LDPE with added butane, are comminuted to spherical beads. After the polyethylene has been cross-linked by an electron beam, the beads are fused continuously with hot air to form foam boards with thicknesses up to 120 mm and apparent densities in the range 28 – 45 kg/m^3. Cell size is about 0.5 mm. This process is used to manufacture Neopolen (BASF) [44], [45].

Batch Processes Using Beads. Pellets of weakly cross-linked LDPE, propylene–ethylene copolymers, or LLDPE in an aqueous dispersion are impregnated with low-boiling (halogenated) hydrocarbons as blowing agents. Impregnation is performed at a temperature near the softening range in the presence of a suspension stabilizer (e.g., tricalcium phosphate, aluminum oxide).

When the pressure is reduced, the particles expand into foam beads with bulk densities of 20 – 70 kg/m^3, depending on the amount of blowing agent and the temperature (Fig. 7) [46], [47]. Uniform cell structure and low bulk densities can be obtained, for example, by posttreatment with nitrogen under pressure [48], [49]. To ensure that the final molded parts have a satisfactory surface, the original pellets should be small (mass, 1 mg) and the beads should have a diameter of 3 – 6 mm. The beads can be processed into molded parts without further cross-linking. This process is used by Kanegafuchi Chemical Industries, Japan Styrene Paper, and Yuka Badische [44], [47].

Processing. Polyolefin foam boards can be cut or split readily with band saws or slicers. They can also be milled, cut thermally, or punched.

By heating and subsequent pressing (hot-melt lamination), cross-linked sheets can be fused to each other or to film, fabric, or sheet metal. They can also be cemented together with rubber-based contact adhesives or elastic melt adhesives. Thermoforming can be carried out effectively on commercial equipment [50–52].

Foam beads can be fused into parts of any desired shape, even boards, without waste by using steam or hot air; the process is similar to that used for expandable polystyrene beads (EPS) (see Section 4.2.1). Additional steps are required to completely fill the interstices between the spheres with foam:

1) In the Neopolen process for molded parts (Fig. 8), beads are placed in the mold cavity at elevated pressure and allowed to expand into the interstices by reducing the pressure. Only then are they exposed to steam, cooled, and removed from the mold [44], [53], [54].
2) The interstitial volume can also be reduced by a movable mold face which compresses the contents of the mold [55].

3) The internal pressure, and thus the expandability of the beads, can be increased immediately prior to mold foaming by using a compressed gas, e.g., nitrogen [56].

Figure 8. Manufacture of molded parts from polyolefin beads

Properties and Uses. Polyolefin foams are predominantly of the closed-cell type. They become semirigid as the crystallinity of the substrate and the apparent density decrease. Because of the air trapped in the cells, PO foams display excellent shock absorption properties which barely deteriorate under repeated impact. During prolonged loading, some of the air escapes from the cells. However, when the load is removed, air diffuses back into the cells and a slow recovery from deformation occurs, which depends on the apparent density and the load. Consequently, polyethylene foams are especially suitable for packaging impact-sensitive goods, e.g., electronic products. In packaging heavy goods, polypropylene foams can support higher loads and thus permit smaller support surfaces than the softer polyethylene foams. Polypropylene is particularly useful when greater dimensional stability under heat is required, e.g., in the automotive sector for items such as bumper cores [57].

The low moisture permeability of polyolefin foams combined with their low water absorption and relatively good weather resistance make them suitable for marine applications (e.g., ship fenders, life buoys, and life jackets) [54]. Protection against UV radiation is recommended for outdoor uses.

Because of their low thermal conductivity, which is only slightly greater than that of other foamed plastics, polyolefin foams are used as flexible pipe covers and insulating bags. More flexible types are used for impact soundproofing and resilient flooring in sports halls [50], [51], [58], [59].

4.1.2. High-Density Polyolefin Foams (250 – 700 kg/m^3)

Low-density polyethylene is foamed with chemical blowing agents (e.g., azodicarbonamide) to give apparent densities up to 450 kg/m^3. This material is used to insulate wires in telephone cables and coaxial cables; its dielectric constant is 3×10^{-4} [60].

Larger, shaped parts with apparent densities of 500 – 700 kg/m^3 can be produced from HDPE and polypropylene by the thermoplastic foam injection molding process. The integral skins of these structural foams gives a higher stiffness than is expected from their mean density [10, pp. 1 – 16].

Polypropylene is also foamed in extruders with chemical blowing agents to produce films and tapes in the density range of 400 – 700 kg/m^3. These products have high surface luster and are used in packaging [10, p. 15], [61].

4.2. Polystyrene (PS) Foams

(→ Polystyrene and Styrene Copolymers)

Polystyrene [*9003-53-6*] (PS) foamed plastics are important because of their physical properties, their broad spectrum of applications, and their favorable price–performance relationship. They can be produced by various processes and with different apparent densities; accordingly, they differ in properties and in possible uses. Trade names of foamed and expandable polystyrene are listed in Table 1.

4.2.1. Expandable Polystyrene (EPS) Foams

Production. The techniques used for the production of expandable polystyrene (EPS) beads and their processing to expanded polystyrene foams were developed at the end of the 1940s by BASF [62] who marketed the new raw material under the trade name Styropor. Due to licensing and the expiry of patents, other raw material manufacturers and trade names have appeared (see Table 1).

Expandable polystyrene is produced by suspension polymerization of styrene with addition of blowing agents; the resulting polymer beads are then sieved into fractions with various ranges of bead size. Depending on end use different coatings may be applied (→ Polymerization Processes).

In addition to pure polystyrene, foams are also made from polystyrene copolymers (e.g., with acrylonitrile or maleic anhydride). These foams possess special properties such as increased solvent or heat resistance. Incorporation of surface coating with organobromine compounds (e.g., hexabromocyclododecane [*25637-99-4*], pentabromophenyl allyl ether [*3555-11-1*]) act as flame retardants and result in flameproofed foams, e.g., Class B 1 building materials according to DIN 4102, M 1 according to NF P 92-505 (Norme Française), or MF-1 according to UL-94 (Underwriter's Laboratories). Blowing agents include low-boiling hydrocarbons, particularly pentane, but also butane, propane, and their mixtures; EPS beads contain 4 – 7 wt % of these substances.

Two other production methods for EPS consist of impregnating standard polystyrene with blowing agents in pressurized vessels and extrusion of EPS or standard polystyrene with added blowing agents. Cylindrical pellets are formed instead of beads.

Processing into Foam. Foam is obtained from EPS in three steps–prefoaming, intermediate storage, and final foaming (or molding)–as illustrated in Figure 9.

During *prefoaming,* the particles are heated and the polystyrene is thereby softened, the blowing agent in the polystyrene evaporates to form rapidly growing bubbles until either the heat supply is shut off or the expandability exhausted [63]. The bead diameter increases about threefold and the bead volume (bulk volume) about thirtyfold. The apparent density of the foamed product is determined by the bulk density obtained during prefoaming.

Intermediate storage is required prior to final foaming into blocks, boards, or molded parts to allow air to diffuse into the individual cells. Air is needed in subsequent molding: it acts as a supplementary blowing agent and also enables the soft cellular structure to withstand the external atmospheric pressure when the finished part is removed from the mold.

Final foaming is usually fully automated [64], [65]: perforated molds are completely filled with prefoamed beads and exposed to steam. The beads expand to fill the residual voids and are fused together. In modern installations, a vacuum is also applied. Some of the water condensed in the foam then evaporates and internal cooling reduces the pressure of the foamed plastic more rapidly, so that the parts can be quickly removed from the mold (short cycle times).

Boards are manufactured batchwise with block molds or with board molding machines; they may also be produced continuously on special moving-belt machines.

The glass transition temperature of polystyrene is reduced if pentane, which acts as a plasticizer, is used as blowing agent. The temperature range used during prefoaming and final foaming is then 85 – 120 °C. The most widely used heat-transfer medium is steam, which has a large heat capacity; it diffuses rapidly through the cell walls, and thus acts as a supplementary blowing agent. In some special cases, hot air is used instead of steam.

Figure 9. Processing of expandable polystyrene (EPS) foam into molded parts and insulation board
a) Prefoamer; b) Intermediate storage; c) Automatic molding machine; d) Continuous foaming unit; e) Automatic board molding machine; f) Block mold; g) Cutter

Foam boards for heat insulation are made primarily from foamed blocks 1 – 6 m^3 in volume. After stabilization for several hours to complete cooling and air uptake, the blocks are trimmed and cut into boards on cutters using electrically heated or oscillating wires. Posttreatment such as grooving or slotting is carried out on milling machines. Sheets of any desired length and 1 – 6 mm thick can be produced from special cylindrical blocks by using peeling machines with rotary blades. These peeled sheets are used under wallpaper and in packaging.

The resilience of boards for impact soundproofing is increased by briefly compressing the blocks prior to cutting or by rolling (or squeezing) the individual boards.

In a number of applications, the foamed plastic must be stored prior to use. This helps to remove internal moisture (steam condensate and residual cooling water) and to reduce postshrinkage of the foam.

Properties. Most of the physical properties of EPS foams depend strongly on the apparent density, the most important are summarized in Table 2. Boards for thermal insulation generally have densities between 15 and 30 kg/m^3, whereas the density of boards used for impact soundproofing is ca. 12 kg/m^3. The density of shape-molded parts is generally 20 – 30 kg/m^3, for special applications it may be much higher.

The chemical resistance of the foams corresponds largely to that of polystyrene.

Uses. Expandable polystyrene foams have many applications including thermal insulation, impact soundproofing [66], and formwork elements for concrete in the building industry; insulation of cold-storage depots and cooling cells, storage and transport tanks, pipes, etc.; and molded parts for packaging [67], promotion articles, toys, and sporting goods. It is also used for producing molded articles by lost-foam casting, a process that is similar to wax molding. A molded EPS form is embedded in sand and molten metal is poured into this composite. The foam shape evaporates and is replaced by metal.

Considerable amounts of nonfused, loose beads are also used as additives in bricks; (during firing they decompose to leave uniformly

Table 2. Physical properties of expandable polystyrene (EPS) foams as a function of apparent density

Property	Testing method	Apparent density, kg/m^3 *				
		15	20	30	60	100

distributed pores). Further uses are as additives in light-weight concrete [68] and as renderings for thermal insulation or as drainage material.

Foamed EPS waste that accumulates during processing can be recycled; it is ground, mixed with preformed beads, and reused during molding. Ground EPS foam has also proved useful for loosening soil, for drainage, and as a filling material. These foams are inert and do not harm ground water, flora, or fauna.

4.2.2. Extruded Polystyrene (XPS) Foams

Foamed polystyrene boards and films are produced in large amounts by extrusion [69].

Production. In the original DOW process [70], polystyrene and a blowing agent were fed into a pressurized autoclave and melted. The molding batch was then cooled to about 100 °C; upon emerging into the atmosphere or into a mold chamber, it foamed and formed a uniform cell structure.

The melting of the polystyrene pellets and the gassing, homogenizing, and cooling of the melt were then performed in extruders [71]. The continuously emerging strand foams, is formed into a flat sheet, solidified in a cooling zone, and cut into boards.

Blowing agents are mainly halogenated hydrocarbons which increase the foam's thermal resistance (decrease thermal conductivity) because of their high molecular mass.

In addition to Styrofoam (Dow Chemical), similar XPS boards with apparent densities of ca. 25 – 60 kg/m^3 are also available, e.g. Styrodur (BASF).

Foam boards are generally dyed during extrusion and provided with flame retardants (e.g., hexabromocyclododecane).

Depending on the end use, the boards are produced with different apparent densities, thicknesses, surface textures (foam skin, milled), and edges (flat, step groove, or groove and tongue).

Properties. The most important physical properties of extruded polystyrene (XPS) foams at different densities are summarized in Table 3. The requirements for use as thermal insulation material in building applications are specified in ISO 4898. The chemical resistance corresponds to that of polystyrene.

Uses. Extruded polystyrene foam boards are expecially suitable for thermal insulation in special constructions where high compressive strength, good appearance in exposed locations, and very low water adsorption are required.

Extruded polystyrene films are produced exclusively by the film blowing process (→ Films). A tubular film is extruded from an annular spinneret. It is then expanded three- to sixfold by using a high internal gas pressure and is thus stretched transverse to the direction of drawoff. The film is then calibrated via a cooling mandrel, cut into one or more strips, flattened,

Table 3. Physical properties of extruded polystyrene (XPS) foams as a function of apparent density

and either wound or processed immediately by thermoforming or lamination.

In the past films were produced in smaller, simple extruders from expandable polystyrene containing a blowing agent. However, the growing demand for such films required the use of large, direct-gassing installations that use standard polystyrene and an added blowing agent as in the extrusion of boards [72]. Low-boiling, preferably nonflammable, hydrocarbons are usually used as blowing agents. Chemical agents (e.g., citric acid plus sodium bicarbonate) and nucleating agents are also added to achieve a uniform cell structure.

Depending on the end use, film thicknesses range from several millimeters to a fraction of a millimeter and apparent densities from 100 kg/m^3 for thick films to 200 kg/m^3 for thin ones.

During thermoforming or lamination with cardboard and other layers, the films are often postfoamed; their apparent density is thus reduced and their thickness is increased. In this way, items such as egg cartons and packaging trays for fruit and meat are obtained with apparent densities of 60 kg/m^3 or less.

Polystyrene film laminated with cardboard is being tested as a replacement for corrugated cardboard where outstanding wet strength is required. Thin films are used for decorative purposes and as nonskid interlayers.

4.2.3. Structural Polystyrene Foams

Special starting materials are available for structural foams derived from polystyrene, its copolymers, and polymer blends. They already contain chemical blowing agents and are specially formulated for thermoplastic foam injection molding (TFI) and thermoplastic foam extrusion (TFE).

Products from butadiene-modified, impact-resistant standard polystyrene and from acrylonitrile–butadiene–styrene (ABS) polymers have the highest usage, followed by structural foams produced from standard polystyrene and styrene–acrylonitrile (SAN) polymers. For a detailed description of these polymers, see → Polystyrene and Styrene Copolymers.

Production. Physical blowing agents in the form of halogenated hydrocarbons are in principle suitable for structural polystyrene foams. However, they have not been widely used because more sophisticated processing technology is required than for chemical agents and control of foam structure is more difficult.

The following chemical blowing agents are commonly used: azo compounds (especially azodicarbonamide, sometimes modified), hydrazines (e.g., benzenesulfohydrazide), and sodium bicarbonate with citric acid.

Cell structure is affected not only by the blowing agents and the processing conditions, but also by the amount and type of nucleating additives such as talc or pigments.

Thermoplastic Foam Injection (TFI) Molding. Molded TFI parts can be produced on conventional injection molding machines with shut-off nozzles. However, low-pressure TFI machines are more economical. The mold is filled in two steps: (1) injection of the melt containing

the blowing agent and (2) postexpansion to fill the mold cavity. Thus, the clamping unit experiences only the expansion pressure which is about one-tenth of the injection pressure required for compact polystyrene. In this two-step process, removal of heat from the melt starts with evaporation of the blowing agent and surface streaks are created on the molded parts. Streaking can be prevented by various techniques, some of which are patented [8].

Thermoplastic Foam Extrusion (*TFE*). The formulations of raw materials used in TFE are similar to those used in TFI. However, since the temperature of the extrusion mass is generally lower, blowing agents with a lower decomposition temperature are used or catalysts are added to promote decomposition of the blowing agent. Although a number of patented extrusion processes exist (e.g., the Celuka process for very smooth surfaces, the Woodlite process for wood-like grain), conventional devices, profiled nozzles, and subsequent calibration are commonly employed [73]. Prior to use, the parts or profiles are frequently subjected to surface treatment such as spraying, printing, or lacquering.

Properties. The physical and chemical properties of structural polystyrene foams depend highly on the raw materials used. With their generally very high apparent densities and virtually compacted surface layers, the mechanical properties of structural foams are only slightly inferior to those of solid parts.

Uses [8]. The major end user of structural polystyrene foam is the furniture industry. The product is not used simply to imitate wood, but to construct structural parts for furniture of modern, functional design that exploits the properties of the raw material. The hi-fi and television industries are also important customers for housings and other TFI components. Significant quantities are also used in the building and transport industries, in the manufacture of sports equipment, and in the automotive sector.

4.3. Poly(Vinyl Chloride) (PVC) Foams

[→ Poly(Vinyl Chloride)]

Depending on the content of plasticizers, polymer processing aids, and thermosetting binders, poly(vinyl chloride) [*9002-86-2*] foams can be flexible, semirigid, or even rigid. Because of their range of properties, PVC foams have numerous uses. Frequently, they form part of structurally complex, multicomponent articles such as floor coverings or window frames.

The composition of PVC foams varies widely. Some consist mainly of PVC and contain only minor amounts of additives necessary for smooth processing and trouble-free application (stabilizers, lubricants, fillers, pigments, or blowing agents and their decomposition products). Others contain larger amounts of modifiers (plasticizers, cross-linking agents, processing aids, or impact modifiers.

Dry blends, granules and fluid or paste mixtures containing blowing agents are used to manufacture PVC foam. The most important processing technologies for dry blends and granules are molding, extrusion, calendering, and injection molding. Fluid or paste mixtures are usually processed by spread coating.

The PVC molding masses are foamed with both chemical and physical blowing agents (see Section 2.2) [74]. The foaming rate can be influenced by kickers or inhibitors. Poly(vinyl chloride) foams cannot be consistently classified because of the different manufacturing processes involved and their broad spectrum of properties and uses. However, division into rigid and flexible PVC foams has proved useful. Semirigid PVC foams are classified as rigid PVC foams although they contain plasticizers.

Trade names of PVC foams are listed in Table 1.

4.3.1. Rigid Poly(Vinyl Chloride) Foams

High mechanical strength, along with resistance to moisture, rot, and chemicals, is common to all rigid PVC foams. Thermal conductivity is $0.036-0.040\,\mathrm{W\,m^{-1}\,K^{-1}}$. These foams have a high oxygen index and their combustion gases contain carbon dioxide, carbon monoxide, and hydrogen chloride.

Most rigid PVC structural foams are produced by extrusion of PVC compound (dry blend or granules containing blowing agents) in the form of pipes, shaped parts, or boards [75–85]. Metal pipes or shapes can also be coated

with foamed PVC by extrusion [86], [87]. Furthermore, rigid PVC foam shapes can be reinforced with glass fibers. Very few rigid PVC foam components are produced by injection molding [88].

In the extrusion of molded rigid PVC parts, processing conditions are adjusted so that the blowing agent foams the molding mass only after it leaves the nozzle. Foamed parts have an outer skin whose thickness and density vary depending on how the melt foams and how rapidly the boundary phase is cooled. Complex shapes and boards of PVC foam can be produced by the so-called Celuka process [89] in which appropriate machine design allows foaming to proceed "inwards".

In the coextrusion process [90], [91], a compact PVC layer (which may be stabilized and pigmented as desired) is melted onto the foam during extrusion as an outer skin. Such profiles are preferred for outdoor use, e.g., as panels.

Rigid PVC foams range from predominantly closed-cell to open-cell, depending on the type and amount of blowing agent and the process used. These foams are used in the building and furniture industries and in the do-it-yourself sector for thermal insulation and as wood substitutes.

Thermoset-modified rigid PVC foams are generally manufactured by a two-step process [92–95]. In the first, so-called high-pressure stage, a paste containing PVC, plasticizer, isocyanate cross-linking agent, stabilizers, and a chemical blowing agent is heated in closed molds to about 180 °C under high pressure. The PVC and the plasticizer then form a gel, and the blowing agent decomposes to form tiny closed cells. After about 1 h, the molds are cooled while the pressure is maintained. In the second, so-called expansion stage, the molded articles containing the blowing agent are exposed to water vapor for several hours at 90 – 100 °C and reduced pressure. The material is still thermoplastic and thus softens; the expansion pressure of the occluded blowing agent increases the volume of the molded article. Some of the isocyanate additive reacts with water to form carbon dioxide which acts as an additional blowing agent; the remainder, together with a special auxiliary system, cross-links the PVC and significantly consolidates the foam structure.

The closed-cell foams produced are used primarily as core materials of high mechanical quality for composites in automotive, ship, and airplane construction. Important manufacturers are Kleber Colombes (France), Airex (Switzerland), and Conti-Gummiwerke (Federal Republic of Germany).

Rigid thermoplastic PVC foams can be produced by the same mold foaming process used for thermoset-modified foams. They are manufactured from polymer granules without using plasticizers, isocyanate, or cross-linking agents. These foams are used as core materials for composites and, because of their closed outer skin, are also used in marine buoyancy or flotation items.

4.3.2. Flexible Poly(Vinyl Chloride) Foams

Flexible PVC foams can be manufactured by various processes, either with or without a carrier.

Flexible PVC foams without support can be manufactured in the same way as rigid PVC foams, by a two-step process using dry blends, granules, or pastes containing blowing agents. The PVC foams obtained are predominantly closed cell; their flexibility and elasticity depend on the cell structure and the plasticizer content. Flexible PVC foams can also be produced continuously but with limited cross section by paste spreading or extrusion.

Flexible foams are used for sealing and insulation in the building trade, for heat insulation and buoyancy in clothing, and for impact protection in sports equipment.

Flexible PVC foams with support are produced by spreading pastes containing blowing agents on various supporting materials. Synthetic PVC leather, for example, consists of a textile carrier, a base layer of flexible PVC, and a layer of flexible PVC foam with a thin, compact surface. The flexible foam layer imparts a soft feel to synthetic PVC leather (→ Leather Imitates).

Modern, chemically embossed, color-printed floor and wall coverings have a similar structure. Inhibitors in the printing ink retard or prevent decomposition of the chemical blowing agent and thus create an embossed pattern that matches the printed pattern [96]. These materials are especially important as floor coverings (Congoleum process) because they are pleasant to walk on (→ Floor Coverings, Chap. 2.3.2.).

A spreadable whipped foam is obtained by intensively whipping gases (nitrogen, carbon dioxide, air) into PVC pastes. This foam is used mainly to back textile or rubber floor covering with an elastic layer that contains largely open pores after gelling [97–99].

Miscellaneous Flexible PVC Foams. Other flexible PVC foam items are produced from pastes containing blowing agents. They are used predominantly as sealing materials. Thus, for example, seals in crowned cork bottle caps used for beverages are produced by gelling and foaming a small amount of PVC paste applied directly to the cap. Similarly, flexible PVC foam seals for industrial components (e.g., air filters for automobiles) can be foamed in situ.

4.4. Foams from Phenol–Formaldehyde (PF) Resins (→ Phenolic Resins)

Production. Phenolic resin foams are produced by the acid-catalyzed, exothermic hardening of a phenol–formaldehyde resin [*9003-35-4*] condensed under alkaline conditions [100], [101] (→ Phenolic Resins). Evaporation of an added (halogenated) hydrocarbon blowing agent by the heat of the reaction produces foaming. Surfactants emulsify the blowing agent and stabilize the expanding foam. The foam is hardened with catalysts such as sulfuric acid, phosphoric acid, or arylsulfonic acids. Hydrochloric acid is no longer used [102]. For complete and thorough hardening, heat treatment may follow [103].

Hydrogen produced by reaction of powdered aluminum with an acid catalyst can also act as a blowing agent. This method is employed in the former Soviet Union where PF foams account for about one quarter of foamed plastic production [104].

Production is predominantly a batch process in which the foaming mixture is poured into block or other cavity molds. The use of spray guns has also been reported [105].

The well-known continuous production of laminated sheets [106] is used by Koppers [107], [108] and British Petroleum Chemicals [109], [110]. Closed-cell foams are presumably created. The starting materials are special resols with a high resin solids content. The blowing agent is a mixture of trichloromonofluoromethane [*75-69-4*] (CFC 11) and 1,1,2-trichloro-1,2,2-trifluoroethane [*76-13-1*] (CFC 113). Alkoxylated silicones [108] or glycerol ricinoleates [110] are used as surfactants.

For hardening, strong organic acids such as an anhydrous mixture of tolyl- and xylylsulfonic acids [108] or 50 % sulfuric acid [110] are used. Special mixing heads have been developed for intensive mixing of components [111].

The mixture is sandwiched between two surface layers of, for example, aluminum-coated cardboard; the foaming mass is shaped and hardened, while still plastic, in a heated, double-belt press (Fig. 10). The pressure exerted in the press is reported to have an important effect on foam quality. It reduces the open-cell content [107] and void formation underneath the upper layer [109].

The resulting laminates are between 30 and 55 mm thick and have apparent densities of 35 – 60 kg/m^3.

Properties. The hard, brittle, thermoset nature of cured PF resin is shared by the foam. It is, however, less pronounced in foams with smaller cells (cell size $< 80\,\mu$m) or with highly perforated cell walls [112].

All PF foams in existence at the end of the 1970s were open-cell types. Here, the cells are interconnected by holes in their walls which are several micrometers wide. Because the holes also allow communication with the surroundings, the cells are air-filled [113–115]. Like polyurethane and polystyrene foams, closed-cell PF foams can now be produced, whose cell walls are intact and free of pores [116], [117]. These cells can thus retain fluorohydrocarbon blowing agents. Because the thermal conductivity of these heavy gases is lower than that of air, the resulting foams are better insulators than air-filled foams (thermal conductivity $< 0.02\,\mathrm{W\,m^{-1}\,K^{-1}}$ and $0.033\,\mathrm{W\,m^{-1}\,K^{-1}}$, respectively).

Figure 10. Production of laminated phenolic foam board
a) Upper surface layer; b) Dispenser for foamable phenolic resin; c) Lower surface layer; d) Upper conveyor belt; e) Lower conveyor belt

Water absorption naturally increases with the number of open cells. Light, largely open-cell PF foams (apparent density ca. 20 kg/m^3) may even be used as floral foam in flower arrangements [118].

If the foam is only partially closed-cell, expensive water-vapor barriers may be needed as, for example, in underground long-distance heating lines insulated with PF foam having an apparent density of 100 kg/m^3 [119]. Infiltration of water would not only impair heat insulation but also initiate corrosion in combination with the acidic hardening agents. Despite the generally high acid content (up to 20 wt %), corrosion problems are seldom encountered, especially with closed-cell products. Corrosion inhibitors such as calcium carbonate can be added.

Over short periods PF foams can resist temperatures up to 180 °C and, over longer periods, up to 130 °C. They are resistant to many solvents and attacked only by concentrated acids or bases.

Compared to other organic insulators, PF foam has a favorable fire behavior primarily because of the low smoke density of its combustion gases and its low flammability. Like other thermosets, the material does not melt. When ignited, a carbon skeleton is formed. With respect to the evolution of toxic gases (carbon monoxide), however, PF foams do not have any advantage over other foamed plastics [100], [101].

The afterglow of open-cell foams (punking) can be suppressed by the addition of flame retardants such as boron trioxide [*1303-86-2*] or aluminum hydroxide [*21645-51-2*]. Closed-cell PF foams hardened with sulfuric acid do not exhibit punking; when burnt, they "pop"; due to the noisy bursting of small particles of material [120].

Uses. In the building industry, for example, PF foam boards covered with glass-fiber webs are used as thermal insulation for flat roofs. They can be processed with hot bitumen because of their high heat resistance. When reinforced with an impregnated paper honeycomb, PF foam serves as the core of structural sandwich elements for walls and roofing, which are capable of bearing static loads. Sheet metal, polyester–glass fiber, plywood, or plaster may be used as surface layers [120–122].

Hemispheres cut from blocks are used for pipe insulation. A pour-in-place process with special molds has also been described [119].

In the former Soviet Union, PF foam is preferred for insulation in transport (motor vehicles, railroad cars, ships) as well as in aeronautic and space applications [104].

Special PF Foams. Inorganic additives (fillers) are added to PF foams to improve their mechanical strength and fire behavior. Depending on the type and amount of filler, *filled PF foams* with apparent densities of 100 – 300 kg/m^3 are obtained. Fillers include expanded silicates such as perlite [*7344-61-8*] [123]. Products that contain phenolic and furan resins are highly filled with materials such as aluminum hydroxide and are used as noncombustible building materials [124].

Phenolic foam with an apparent density of 20 – 30 kg/m^3, which is filled with polystyrene foam beads, can be obtained by dielectric heating [125].

Hybrid foams with good mechanical properties and low combustibility can be produced from PF resins and polyisocyanates [126].

4.5. Foams from Urea–Formaldehyde (UF) Resins (→ Amino Resins, Chap. 7.1.)

Production. A surfactant solution containing a hardener (e.g., phosphoric acid) is foamed with compressed air and blended with an aqueous 30 – 40 % solution of urea–formaldehyde resin [*9011-05-6*]. The resin is distributed throughout the surfactant foam, and cross-linking is initiated by the acidic hardener. A light, whipped-cream-like foam is formed which can be shaped easily and used to fill any cavity. The foam hardens rapidly to a water-insoluble, rot-resistant, foamed plastic without creating expansion pressure [127], [128]. A hardening time of 15 – 40 s is generally selected, which can be controlled within certain limits by changing external variables (temperature, hardener concentration).

Newly formed foam contains ca. 70 – 75 wt % of water. During drying, cracks are formed in the lamellae and the foam becomes open-celled [129]. This is accompanied by a ca. 8 % decrease in volume which can be reduced to 3 % by additives (e.g., polyols) [128], [130], [131]. Any free formaldehyde remaining is lost along with the water. Problems caused by formaldehyde release can be avoided largely by using more urea or improved resin formulations [132–134].

Stationary and portable equipment is available for foaming. Insulating layers can thus be introduced in cavities that are not easily accessible (e.g., in double walls).

Properties. Apparent densities of UF foam range from 10 to 30 kg/m^3 depending on the application. It can support little or no mechanical load and is, therefore, not used as semifinished product.

Urea–formaldehyde foam can withstand continuous exposure to temperatures up to 100 °C; at higher temperature, gradual shrinkage occurs. This material decomposes above 200 °C [128].

The thermal conductivity of UF foam (ca. 0.035 W m^{-1} K^{-1}) is in the same range as that of other air-filled insulating foams (cf. Fig. 3).

The material has a relatively favorable oxygen index (cf. Fig. 4). Although UF foam does not meet the flammability requirements of DIN 4102, it performs better in other flammability tests [ASTM D 1692-59 T, BS 2782 (1985) 508 D] [128].

Uses. The apparent density of in situ UF foam used in buildings must be at least 11 kg/m^3 (DIN 18 159). The foam serves mainly as thermal insulation in wall cavities [129], [135] and in plumbing ducts [136].

In mining, cavities (e.g., gallery roofs) are filled with UF foam to prevent accumulation of dangerous firedamp [137], [138]. The foam is also employed in the construction of airtight dams to seal off sections of mines (e.g., abandoned shafts) [139].

In agriculture and horticulture, UF foams with apparent densities > 20 kg/m^3 and preferably in the form of flocks (e.g., Hygromull, BASF) are mixed into the soil to improve heat balance. Because of their open-cell structure, the foams also store water and dissolved nutrients.

Kindling is obtained by emulsifying liquid petroleum products with UF foam during manufacture [140].

Foamed plastic with an apparent density of ca. 30 kg/m^3, ground to a particle size of 0.1 – 6 mm and containing a surfactant and an antistatic agent, is used in carpet cleaning [141].

Urea–formaldehyde foam is suitable for cushioning impacts only if no more than one violent impact is anticipated (parachute deployment) [142]. For trade names of UF foams, see Table 1.

4.6. Foams from Melamine–Formaldehyde (MF) Resins (→ Amino Resins, Chap. 7.2.)

The rigid, brittle melamine–formaldehyde resin [*9003-08-1*] foams known until the late 1970s had no practical significance [143]. However, a flexible, elastic foam can now be produced from the same resin. This foam (Basotect, BASF) has a completely different morphology [144], [145]; it is open-celled and has slender, flexible struts (cf. Fig. 2B). The length : diameter ratio of the struts is crucial to its elastic behavior. For strut

diameters from 7 to 15 µm, the ratio must exceed 10.

Production. A surfactant is used to emulsify pentane with a melamine–formaldehyde precondensate (molar ratio 1 : 3). Hardening occurs upon addition of formic acid. Controlled expansion in a continuous foaming tunnel is initiated by heating [146], [147].

Pentane and water from the reaction mixture act as blowing agents [148]. After removal of water and pentane, the foam is perfused continuously with hot air at 220 – 250 °C, and any cleavable formaldehyde is completely eliminated [149]. Flexible foams result only if the solids content exceeds 70 % [146]. Brittle products are obtained if the solids content is lower.

Properties. Density ranges from ca. 10 to 12 kg/m^3. Morphology and, hence, mechanical properties can be modified by pressing, which slightly bends the originally straight struts. The material becomes more flexible, with a negligible increase in density. For example, the compressive stress at 40 % deformation drops from 1.1 to 0.8 MPa [150]. Extreme mechanical–thermal treatment produces a highly consolidated, weblike material [151].

Because of the large proportion of IR radiation scattered by the thin struts, the thermal conductivity of the foam is in the lower range of air-filled insulators (Fig. 3).

Melamine resin foam can withstand short exposure up to 250 °C and long exposure up to 150 °C. No solvents are known for the foam; it is attacked by concentrated acids and bases.

Water absorption and diffusion properties are similar to those described in Chapter 3 for open-cell foams. The open, extremely fine structure and the flexibility of the foam result in especially favorable acoustical properties; despite the low apparent density, these properties are similar to those of open-cell polyurethane foams and mineral fibers.

The material meets the requirements of flammability class B 1 building materials, specified in DIN 4102 ("schwer entflammbar," i.e., of low flammability), without an added flame retardant. According to the tunnel test of ASTM E 84-82 A, it is a class A material as defined in the Standard Building Codes. The smoke density of the combustion gases is low but does not reach the minimum values of PF foam. The material carbonizes during burning, without melting, and decomposes above 350 °C [145].

Uses. Thermal insulation, heat resistance, and ease of processing have opened up many applications for MF foams in industrial heat insulation (e.g., pipe insulation).

The material is used for sound insulation in the form of decorative ceiling and wall paneling, as well as for casings in automotive engines. Because of its low dynamic stiffness, MF foam is also employed for impact sound insulation. Laminates with plasterboard provide good soundproofing in addition to the desired thermal insulation.

4.7. Silicone (SI) Foams

Production. Silicone foams are produced from hot- or cold-vulcanized silicone rubber (→ Rubber, 5.Technology, Chap. 2.5.2.2., → Silicones).

Heat-activated vulcanization systems contain mostly high molecular mass polysiloxanes incorporating methyl as well as vinyl groups. Additional components are chemical, heat-activated blowing agents, peroxide cross-linking agents, and silicate fillers [152]. These "single"-component blends are stable at room temperature and begin to foam when vulcanized by the action of heat.

Generally, preforms of the mixture or previously formulated dry blends are foamed in compression molds or extruders at 150 – 200 °C. The particles of silicone foam are then annealed at ca. 200 °C to remove any decomposition products derived from the cross-linking agent and to complete residual cross-linking.

Room-Temperature Vulcanization (*RTV*) *Systems.* Pourable mixtures that can be vulcanized and foamed at room temperature are required for producing molded articles and for filling cavities or coating parts with silicone foam.

Two-component systems are used in which short-chain polysiloxanes containing Si – H groups are allowed to react with low-viscosity polysiloxanes containing Si – OH groups. The reaction is performed at room temperature in the presence of a condensation catalyst:

$$\equiv Si-H + \equiv Si-OH \xrightarrow[\text{Room temp.}]{\text{Catalyst}} \equiv Si-O-Si\equiv + H_2$$

The hydrogen evolved acts as a blowing agent, but additional blowing agents may be necessary. Organotin compounds are used as catalysts [153], [154]; platinum catalysts yield products with improved heat and fire resistance [155–157].

The degree of cross-linking and the morphology of the foam can be controlled by the ratio of silanol to silane groups, especially by their functionality. Foams that range from rigid to flexible and from largely open-cell to closed-cell can be produced this way [158].

The above reaction takes only a few minutes but can be retarded by using acetylene alcohols or rhodium compounds as catalyst. The system is then stable for several hours and can be reactivated with heat [159].

Foam systems that can be cross-linked with atmospheric moisture have also been described [160].

A froth produced from a silicone emulsion can be converted to a light, elastomeric silicone foam in a microwave oven; no additional blowing agent is required [161].

Properties. Silicone foams are produced with apparent densities of 60 – 300 kg/m^3, but highly filled products are heavier. The heat distortion temperature is at least 200 °C; the material generally decomposes above 350 °C although higher limits have been recorded [162]. Thermal conductivity is reported to be 0.035 – 0.07 W m^{-1} K^{-1}.

Silicone foams display largely constant cushioning properties over a wide temperature range (− 80 to + 200 °C), and compression set is low. These materials exhibit good dielectric properties; are resistant to hydrolysis, radiation, aging, and weathering; and are physiologically inert.

The materials have a high flame resistance, with a favorable oxygen index of about 30 and a low smoke density. Combustion gases contain only carbon monoxide and carbon dioxide.

Uses [157]. Examples of the uses of silicone foams are

- sealing (shaped profiles, strings, rings) including heavy-duty applications in nuclear power plants;
- filling cracks or cavities, and sealing cable inlets and outlets in construction work;
- thermal and electrical insulation of fragile components in aerospace applications, with simultaneous vibration damping;
- production of carbonizing heat shields used in space vehicles (filled foams) [163];
- cushioning in airplane seats [162]; and
- fitting artificial limbs and producing inert implants for medical use [164].

4.8. Epoxy (EP) Foams (→ Epoxy Resins)

Production. The starting components for epoxide foams are epoxide oligomers, cross-linking agents, blowing agents, surfactants, and possibly also fillers. Silicone–glycol copolymers are described as surfactants [165]. The preferred epoxide oligomers are reaction products of 2,2-bis(4-hydroxyphenyl)propane [*80-05-7*] (bisphenol A) and epichlorohydrin [*106-89-8*] (→ Epoxy Resins, Chap. 2.1.). Cross-linking agents include fast-acting aliphatic amines (e.g., diethylenetriamine [*111-40-0*]) or slower acting aromatic amines (e.g., 1,3-phenylenediamine [*108-45-2*]) that are effective only at elevated temperature. The reaction is highly exothermic and thus activates the blowing agent which is often a fluorinated hydrocarbon or a compound that splits off nitrogen (e.g., sulfonyl hydrazides). Precise temperature control during foaming is important. Too high a temperature causes cracking and deformation of the foam.

Foams with apparent densities of 20 – 40 kg/m^3 are produced from fast-acting systems by a two-component spray process. However, mold-pouring or injection processes are more common and can also be used with slow-acting systems that require external heat. The resulting foams have apparent densities of 60 – 300 kg/m^3 [166]. Trade names are listed in Table 1.

Syntactic foams (see also 1) [167] often consist of epoxy resins and, therefore, are discussed in this section. Their cells are formed by hollow spheres (microballoons) that are distributed in the polymer matrix as a filler. The hollow spheres are composed of glass or phenolic resin and have a diameter of ca. 100 µm and a wall thickness of ca. 2 µm. Larger "macrospheres" composed of epoxy resin and with a diameter of over 1 mm have also been described [168].

The hollow spheres are mixed with a low-viscosity epoxy resin in the same way as fillers. When the fraction of spheres is 40 vol % or less, mold pouring is used for further processing; extrusion or compression molding can be employed for fractions up to 67 vol %. A vacuum is applied for degassing. The products have apparent densities of 200 – 800 kg/m^3.

Phenolic resins, polyimides [169], silicones [170], and polyether sulfones are also used as matrix resins.

Properties and Uses. Epoxy foams are usually rigid and primarily closed-cell materials. They have favorable mechanical properties, absorb very little water, and are not hydrolyzable. They are resistant to many chemicals but not to ketones.

The good adhesion of EP foams to many materials makes them suitable as laminate cores. They also serve as edge seals for honeycombs made from materials such as the aramid Nomex that are used in airplane construction.

Because of their low dielectric constant (< 2), EP foams are used in protective housings for radar equipment (radomes). Materials with a higher dielectric constant are obtained by addition of metal flocks (e.g., aluminum) and are used as radar lenses.

Sensitive electronic components are protected by encapsulation in EP foam [165].

The heat distortion temperature is reported to be 100 – 200 °C. The thermal conductivity of EP foams containing heavy gases is ca. 0.02 W m^{-1} K^{-1}, whereas that of foams manufactured with other blowing agents exceeds 0.035 W m^{-1} K^{-1}, depending on the density. Therefore, these foams are also used as insulation for hot-water pipes.

Epoxy foams that do not contain fire retardants are flammable. The oxygen index is 20.

Syntactic foams are very rigid and able to withstand very high hydrostatic pressures. They are employed in laminates for underwater vehicles, including a shuttle for deep-sea mining to a depth of 6000 m. Other uses include flotation devices with a density of 0.5 g/cm^3 for steel pipes in offshore oil exploration [168], and ablation materials for space flight.

4.9. Polyimide (PI) Foams (→ Polyimides)

The increasing importance of polyimides as temperature-resistant materials has led to the development of PI foams. Trade names are listed in Table 1.

Production. In a typical polyimide synthesis, the hemiester (**2**) is prepared from 3,3′,4,4′-benzophenonetetracarboxylic acid dianhydride [*2421-28-5*] (**1**) and ethanol. The polyimide (**4**) is obtained by reacting **2** with a diamine, in this case 4,4′-diaminodiphenylmethane [*101-77-9*] (**3**) (and if necessary with 2,6-diaminopyridine [*141-86-6*]), in the presence of suitable surfactants.

The powder obtained after spray-drying the precursor solution is foamed into large blocks in a microwave oven. The water and alcohol liberated upon imidization act as blowing agents.

Flexible, open-cell foams are formed [171]. Morphology and especially thermal properties can be modified by using other diamines containing, for example, hexafluoropropyl groups [172], [173].

Rigid panels can be produced by impregnation of fibrous webs or honeycombs with precursor solution and subsequent foaming. Syntactic PI foams (cf. page 22) and rigid PI foams [174] are also known.

Properties. The range of apparent densities of flexible PI foams is 6 – 18 kg/m^3; the thermal conductivity is ca. 0.035 – 0.040 W m^{-1} K^{-1} at 10 °C.

The materials are resistant to solvents. They do not undergo hydrolysis and can be used between − 195 and + 260 °C. Their fire behavior is particularly favorable: they have a very low smoke density and a high oxygen index [175–177].

Uses. Lower density PI foam is used for acoustic and thermal insulation. Its low mass and fire behavior make it highly suitable for aerospace applications [178] where material cost is not a primary concern.

Examples of uses are as a heat and vibration protection for sensitive military and aerospace electronics equipment, a lightweight fire barrier

for airplane cabins, and cryogenic insulation for fuel tanks. The higher density foams can replace polyurethane foams in airplane seats because of their cushioning properties [179]. Uses in shipbuilding have also been reported.

4.10. Polymethacrylimide (PMI) Foams

(→ Polyimides)

Methacrylic acid [*79-41-4*] and methacrylonitrile [*126-98-7*] are subjected to radical copolymerization after the addition of blowing agents (e.g., formamide, or 1-propanol) that will come into play later. A transparent sheet is formed which is heated in a second step to 175 – 220 °C.

Copolymer of methacrylic acid and methacrylonitrile — Polymethacrylimide [*53112-45-7*]

Heating results in imide formation and the production of a rigid, closed-cell foam (Rohacell, produced by Röhm, Federal Republic of Germany) [180–182].

Properties. The relatively rigid material has apparent density of 30 – 200 kg/m^3. The heat distortion temperature (180 °C) can be increased to ca. 205 °C by annealing, which increases the degree of imidization. While warm, the foamed plastic can be reshaped and compacted. The thermal conductivity is 0.030 – 0.034 W m^{-1} K^{-1}.

Polymethacrylimide foam is resistant to organic solvents but attacked by alkaline media. The material burns, giving off little smoke; its oxygen index is 20.

Uses. Polymethacrylimide foam serves as a core material for lightweight laminates with high flexural rigidity which can be loaded dynamically. Because the foam is thermoplastic and can be compacted, complex forms can be produced with precision from a preform in a press. Therefore, the product frequently simplifies existing fabrication techniques. It is used in skis, tennis racquets, helicopter rotor blades, and load-bearing parts in airplanes.

Components with a large surface area (e.g., for railroad car construction) can be produced from sheet-molding compound sandwiches in short cycles at a molding pressure of ca. 1 MPa [183–185].

4.11. Poly(Methyl Methacrylate) (PMMA) Foams (→ Polymethacrylates)

Production. Monomeric methyl methacrylate [*80-62-6*] is subjected to radical polymerization in the form of a thin layer between glass plates. It contains trichlorofluoromethane or pentane as a blowing agent and butyl methacrylate as a plasticizer. A board is formed (typical thickness 4 mm) which is subsequently foamed at 110 °C [186].

Properties. The foamed sheets (typical thickness 16 mm) have very large closed cells (diameter 2 – 10 mm) and thus absorb very lit-

tle visible light. Material with an apparent density of 30 kg/m^3 has a thermal conductivity of 0.035 – 0.044 W m^{-1} K^{-1}. It is highly weather resistant.

The maximum long-term service temperature of the PMMA foam Isocryl (IMC Acrylguß) is 80 °C.

Uses. The transparent insulating material is used for double-glazing improvements to increase the thermal insulation of windows in large buildings and greenhouses. It is also used in ceiling construction [187].

4.12. Polyamide (PA) Foams

(→ Polyamides)

Production. A structural foam with only slightly lowered apparent core density (1.1 → 1.0 kg/m^3) is produced by the reaction injection molding (RIM) process. Caprolactam [*105-60-2*], for example, is injected into a mold with sodium lactamate [*2123-24-3*] as catalyst and an acyl lactam as activator [188–190]. Nitrogen serves as blowing agent [191]. Reaction injection molding permits good filling of the mold with low postshrinkage of the molded part. No sink marks are formed.

Foams with apparent densities down to ca. 400 kg/m^3 are made by conventional thermoplastic injection molding from polyamide (nylon 6) and a second batch containing blowing agents (e.g., azocarbonimide) [192], [193].

Polyamide foams with apparent densities below 200 kg/m^3 can also be obtained by alkaline lactam polymerization with low-boiling hydrocarbons as blowing agents [192–195]. However, they have no commercial significance.

Properties and Uses. Polyamide foams with higher apparent densities are used more widely than those with low densities, and their properties resemble more closely those of solid polyamides. Their toughness, rigidity, and abrasion resistance are worthy of mention. The high heat resistance, solvent resistance, and relatively favorable fire behavior are additional advantages. The inherent water absorption of polyamides can alter the mechanical and thermal behavior of the foam.

Some applications of structural PA foams are as housings for electrical apparatus, lamp sockets, furniture parts, pallets, containers, and bowling pins. Trade names are listed in Table 1.

4.13. Poly(Phenylene Oxide) (PPE) Foams [→ Poly(Phenylene Oxides)]

Blends of poly(phenylene oxide) [*25667-40-7*] with high-impact polystyrene are fabricated into structural foams by thermoplastic foam injection molding. Trade names are listed in Table 1.

The material is distinguished by good mechanical properties and a high heat resistance. The polystyrene content has an adverse effect on the favorable fire behavior of PPE (oxygen index = 30).

Applications in the automobile sector (crash pads) and in computer manufacture have been described [10, p. 16].

In the patent literature, the manufacture of extruded, lighter weight foams from PPE – PS blends, by using chlorinated hydrocarbons as blowing agents, is described [196].

4.14. Polysulfone (PSU) Foams

(→ Specialty Plastics)

Production. In the *dough-foam process,* particles of polysulfone [*25135-51-7*] are allowed to swell and form a gel in a solvent such as methylene chloride or a ketone. A cold-extruded dough sheet is comminuted to dough pellets, which can then be processed into foam-molded parts by using EPS technology (cf. Section 4.2.1). The gel can also be pressed directly to give a preform which foams when heated. Heating causes the solvent or blowing agent to escape and the low glass transition temperature of the gel increases to the high polysulfone value of ca. 200 °C [197–199].

Properties and Uses. The apparent densities of PSU foams are between 40 and 500 kg/m^3, depending on the process used. Unfilled products made by the dough-foam process, for example, have apparent densities of 390 kg/m^3; fiber-reinforced foams may have apparent densities as high as 700 kg/m^3.

Polysulfone foams display high heat resistance and a favorable fire behavior.

Possible applications include self-lubricating bearings, as well as special laboratory and medical products.

Highly filled syntactic polyether sulfone foams have been proposed for radomes [200].

4.15. Polycarbonate (PC) Foams

(→ Polycarbonates)

Production. Structural polycarbonate [*24936-68-3*] foams with apparent densities of 560 – 900 kg/m^3 are produced by low-pressure thermoplastic foam injection molding. Special chemical blowing agents [201] are admixed prior to processing which occurs at about 300 °C [202].

The manufacture of lighter weight foams by extrusion with chlorinated hydrocarbon blowing agents has also been described [203].

Properties and Uses. Polycarbonate foams, like the solid material, exhibit high impact resistance, rigidity, and heat resistance. They are flame-resistant and have a high electrical resistance. They are resistant to acid, but are attacked by bases, and by aromatic or halogenated hydrocarbons.

Examples of applications are housings for electrical apparatus, sports equipment (water skis), and furniture parts. Trade names are listed in Table 1.

5. Testing (→ Plastics, Properties and Testing)

Almost all major industrialized countries have adopted their own standards for testing foamed plastics (e.g., ASTM, United States; BS, Great Britain; DIN, Federal Republic of Germany; Association Française de Normalisation AFNOR, France). International standards (ISO) also exist. In some countries, test methods are specified in end-use-related standards. Thus, for example, foams for the building industry and their test methods are specified in ASTM C 578 "Standardized Specification for Preformed, Cellular Polystyrene Thermal Insulation."

In this overview, only the principles of the most important, generally valid test methods are described. Detailed information necessary for actual testing must be obtained by referring to the standards listed.

5.1. Mechanical Properties

Density (ASTM D 1622, ASTM C 303, ISO 845, DIN 53 420). The density is determined by using cubical test specimens or slabs; it is measured in kilograms per cubic meter.

Open- and Closed-Cell Content (ASTM D 2856). The content of open and closed cells is determined by measuring the apparent and true volumes with a special apparatus. The fraction of open or closed cells is reported in volume percent.

5.1.1. Rigid Foams

Compressive Properties (ASTM D 1621, ISO 844, DIN 53 421). The *compressive stress* is the compressive load per unit area of minimum original cross section carried by the test specimen at any given moment (Fig. 11). It is expressed in force per unit area, e.g., newtons per square meter or pascals. The *compressive strength* is the stress at the yield point (the first point on the stress–strain curve at which an increase in strain occurs without an increase in stress). In the absence of such a yield point, the compressive strength is the stress at 10 % deformation.

Figure 11. Typical stress–strain curve for a foamed plastic

Tensile Properties (ASTM D 1623, ISO 1962, DIN 53 430). The *tensile strength* σ_B is obtained by dividing the breaking load in newtons by the original minimum cross-sectional area of the specimen in square centimeters. The *elongation* is the extension of the material at the moment of rupture expressed as a percentage of its original length measured between gauge marks. The shape of the test specimen used depends on the amount of sample available, as well as the stiffness of the material. It may be round or square and have tapered ends or rounded shoulders; length varies from 10 cm to 1 m. A typical shoulder shape is shown in Figure 12. Speed of testing strongly influences the results; a standard speed is chosen such that rupture occurs in 1 – 6 min.

Figure 12. Specimen for tensile testing
All lengths are given in millimeters.

Breaking Load and Flexural Properties (ASTM C 203, ISO 1209, DIN 53 423). The breaking load and flexural properties are tested by different procedures on a bar of rectangular cross section which can be loaded in two ways:

1) The bar rests on two supports and is loaded midway between the supports.
2) The bar rests on two supports and is loaded at the two quarter points.

Normally, values are measured at the maximum load or breaking point. The *flexural strength* is equal to the maximum stress in the outer layers at break; it is calculated from the load applied at the break point by means of equations that depend on the testing procedure used. Flexural properties may vary with specimen span-to-thickness ratio, temperature, difference in rate of straining, and testing procedure followed. In comparing results, these parameters must be consistent.

Dynamic Stiffness (DIN 52 214). The dynamic stiffness of elastified rigid foams is easily measured and is used to estimate their potential as impact soundproofing material. A metal plate that applies a 2 kPa (kN/m^2) load uniformly to the test specimen is affixed to it with plaster. An alternating force is applied perpendicular to the metal plate. The resonance frequency f_r of the system is measured. The dynamic stiffness s' is proportional to f_r^2.

5.1.2. Flexible Foams

Several procedures are used to test the compressive behavior of flexible foams.

Compression Load Deflection Test (ASTM D 1564, ASTM D 2406, DIN 53 577). This test involves measuring the load necessary to produce a defined compression (20, 40, or 60 %) over the entire surface area of the foam specimen. The compressive stress at the specified compression is given in pascals or newtons per square meter. The test is also used to measure the relaxation of flexible foams after removal of the compressive load.

Indentation Load Deflection (ILD) (ASTM D 1564, ASTM D 2406, DIN 53 576). This test measures the load necessary to produce a defined indentation (e.g., 25, 65, or 70 %) in the foam product. A flat, circular indentor foot of specified diameter is connected to a load-measuring device by means of a swivel joint and is pressed into the specimen. The force in newtons required for 25 and 65 % indentation is known as the 25 and 65 % ILD value, respectively.

The ASTM tests also describe a procedure for measuring indentation on loading. These values are known as indentation residual gage

load (IRGL) values. The load deflection is determined by measuring the thickness of the foam under fixed loads on a circular indentor foot.

Compression Set Test (ASTM D 1564, ASTM D 2406, DIN 53 572). This test involves compressing the foam specimen under specified conditions of time and temperature, and noting the effect on the thickness of the specimen. The compression device consists of two or more flat plates arranged so that the plates are held parallel to each other by bolts or clamps; the space between the plates can be adjusted to the required thickness by means of spacers.

Standard testing conditions are a compression of 50 or 75 %, a temperature of 70 °C for 22 h, and a relaxation time of 30 min. The constant-deflection compression set is calculated and expressed either as a percentage of the original thickness or as a percentage of the original deflection.

Tensile Properties (ASTM D 1564, ASTM D 2406, DIN 53 571). Tensile stress, tensile strength, and elongation at break are measured when a tensile load is applied to the foam. The test specimen is stamped out with a die of a specified shape (shoulder shape, see Fig. 12). The *tensile stress,* in pascals or newtons per square millimeter, at a given elongation is the load applied at this elongation divided by the original cross-sectional area of the specimen. The *tensile strength* is the tensile stress at the breaking point.

Resilience (Ball Rebound) Test (ASTM D 1564). The ball rebound test is used to evaluate the resilience of foams; a steel ball is dropped on a foam specimen, and the height of rebound is noted. Values are given as a percentage of the dropping height and are known as ball rebound resilience (BRR) values.

5.2. Thermal Properties

Dimensional Stability (ISO 2796, DIN 53 431) consists of measuring the dimensions of a test specimen at a standard test temperature (e.g., − 25, 0, or +70 °C). The change in linear dimensions is expressed as a percentage of the values measured at room temperature.

Compressive Creep (ISO/TR 2799, ISO 4898, DIN 18 164) consists of measuring the change in thickness of a test specimen when it is subjected to a load at elevated temperature. The change is given as a percentage of the original thickness. Several testing procedures are used; common testing conditions follow.

t, °C	Load, kPa	Time, h
70	0	48
80	20	48
70	40	168

Deflection Temperature (ASTM D 648, DIN 53 424) consists of determining the temperature at which an arbitrary deformation occurs when a specimen is subjected to an arbitrary set of testing conditions. Either a compressive or a flexural load may be used.

Flexural Load. A bar of rectangular cross section is tested as a simple beam; the load is applied at its center, or the bar is held at one end while the load is applied at the other. The loaded specimen is immersed in a heat-transfer medium whose temperature can be increased at a constant rate (e.g., 2 °C/min or 50 °C/h). The temperature of the medium is measured when a certain deflection (e.g., 2 mm) has been reached and is recorded as the deflection temperature under flexural load.

Compressive Load. A test specimen of 50×50×20 mm is loaded with 25 kPa (0.025 N/mm^2). Then, as with flexural load, the temperature of the test specimen is raised at a constant rate (e.g., 50 °C/h). The temperature at which a certain deflection is reached is recorded as the deflection temperature under compressive load.

Thermal Conductivity (DIN 52 612, ASTM C 177, ASTM C 518, ASTM C 236). The thermal conductivity, expressed in watts per meter per kelvin, is the rate of heat flow through a unit thickness of an infinite slab of a homogeneous material in a direction perpendicular to the surface, induced by a unit temperature difference.

Thermal conductivity is one of the most important properties of foamed plastics and is generally low due to their cellular structure.

Because of the technical importance of this property and the complicated nature of the

measurements, different test methods exist. In principle, a steady-state heat flux is measured through flat slabs of the specimen using a guarded hot-plate apparatus. Single-sided and double-sided modes of measurement are used. An idealized double-sided system is shown in Figure 13. The specimen is sandwiched between two isothermal cold plates and a guarded hot plate. The guard portion of the isothermal hot plate provides the power necessary to create the proper thermal conditions within the test volume.

Figure 13. Schematic of the guarded hot-plate apparatus for determining thermal conductivity
a) Cold isothermal surface; b) Hot isothermal surface; c) Specimen; d) Isothermal planes; e) Heat flux lines

A good review of terms, definitions, symbols, and units pertaining to thermal insulating materials is given in ASTM C 168.

Fire Behavior. The fire behavior of foamed plastics depends on many parameters. Therefore, many different tests exist, each of which emphasizes different aspects of burning, i.e. ease of ignition, flame propagation, heat release, combustion products (smoke density and toxicity). The most important tests are DIN 4102, DIN 53 438, ASTM E 84, NF P92 501, NF P92 504, NF P92 505, NF P92 506, UL 94, ASTM D 2863-77.

5.3. Miscellaneous Properties

Water absorption (ASTM D 2842, ISO 2896, DIN 53 433) of cellular plastics is determined by measuring the change in buoyancy resulting from immersion under a head of water for a certain time (2 h, 4 d, 7 d, 28 d, or longer). Water absorbed by the specimen lowers buoyancy by reducing the volume of water displaced. Water absorption may be expressed in volume percent or weight percent.

Thermal and Humid Aging (ASTM D 2126). Because of the wide variety of potential uses of cellular plastics, artificial aging tests must be based on the intended application. Normally, responses to temperature and humidity are selected. Temperature ranges from − 70 to + 200 °C and humidity ranges from ambient to 97 % are used. The specimen is examined visually; changes in density and dimensions are also measured.

Electrical properties of foamed plastics are seldom measured. Testing methods are identical with those used for standard plastics (see → Plastics, Properties and Testing).

Table 4. Consumption of foamed plastics in 1986

Foamed plastics *	Consumption, 10^3 t		
	Western Europe	United States	Japan
Expanded polystyrene (EPS)	485	283	190
Extruded polystyrene (XPS)	135	293	300
Poly(vinyl chloride) (PVC)**	25	150	
Polyolefin (PO)	20	25	37
Urea–formaldehyde (UF) resin	12		
Phenol–formaldehyde (PF) resin	10	8	3

* Foamed plastics with an apparent density of $< 200\,kg/m^3$.
** Including foams with apparent density $> 200\,kg/m^3$.

6. Economic Aspects

Polyurethanes are the most important foams as far as consumption is concerned and are described elsewhere (→ Polyurethanes). The consumption of other major foamed plastics in Western Europe, the United States, and Japan is summarized in Table 4. The most important of these are foams derived from polystyrene beads and extruded polystyrene. Significant amounts of foam from polyolefins, poly(vinyl chloride), phenol–formaldehyde resins, and urea–formaldehyde resins are also used.

7. Toxicology and Environmental Aspects

The polymeric materials used for foamed plastic production generally do not present a toxicological hazard because they are not absorbed by

the human body. Of greater concern are residual monomers and additives, i.e., materials of lower molecular mass. All legal requirements pertaining to such constituents must be observed. For the benefit of processors and end users, the manufacturers of synthetic foams provide pamphlets, safety bulletins, and technical information on the processing and proper handling of synthetic foams.

Foamed plastic waste is bulky and is therefore often compacted before disposal. Since toxic substances are not released on storage, contamination of ground water does not occur. After being dumped the foamed plastics are slowly degraded, the rate depending on the nature of the plastic [204]. During the controlled aerobic degradation of noncomminuted thermoplasts and thermosets (composting), soil-inhabiting Actinomycetes were shown to attack aminoplasts most effectively [205].

Although foamed plastics have a high calorific value, they do not play an important role in refuse incineration plants because of their low mass. However, thermoplastic foams must be mixed with sufficient quantities of nonmelting materials with a low calorific value.

The combustion products of most foamed plastics are carbon dioxide and steam which do not pose any environmental problems. However, chlorine-containing products release hydrogen chloride which must be removed by washing the flue gas [206].

Chlorofluorocarbons (CFCs) are used in the production of many foamed plastics. They remain enclosed within the cells of the plastic and increase the thermal insulation of air-filled foams.

The ozone depletion hypothesis [207] suggests that CFCs damage the stratospheric ozone layer that prevents shortwave UV radiation from reaching the earth. Models of stratosphere chemistry, propose as many as 200 possible reactions that involve CFCs, carbon dioxide, nitrogen oxides, and methane. Chlorine atoms seem to play an important role in initiating ozone-consuming reactions [208–210].

"Soft" CFCs (e.g., chlorodifluoromethane [*75-46-6*]) are being introduced as alternative blowing agents. Since they are less stable than the customery CFCs, they are reported to decompose in the troposhere and thus have a much lower ozone depletion potential [211], [212].

1. Introduction

In a number of contexts, foaming is considered a desirable phenomenon. The food and beverage industries are well aware of the wholesome connotations associated with the foamy head on a glass of beer or such foams as whipped cream and meringue. Generations of housewives have assumed that foam is evidence of a detergent's cleaning power. *Meerschaum* provides another interesting example. It is a form of sepiolite [*61180-58-3*] prized as a decorative basis for pipes, and its common name means "sea foam" in German. Other solid foams are important for their use as insulating or lightweight construction materials (→ Foamed Plastics).

Nevertheless, foam is often very undesirable: it can severely hinder the filling of a container, reduce the efficiency of many high-speed operations, and cause surface defects in coating operations. Various terms such as *foam inhibitor, antifoaming agent, foam controller,* and *defoamer* are applied to substances designed to prevent or control foaming, but the distinctions are somewhat vague and a given material often serves both preventive and control functions.

Figure 1. Schematic representations of the major types of foam [9]
A) Spherical-bubble foam; B) Polyhedral foam

2. Theory of Foam and Foam Control

2.1. Characteristic Properties of Foam

A foam consists of gas dispersed within a liquid. Pure liquids are incapable of foaming; soluble surfactants or impurities [8] are required to stabilize a foam by retarding the otherwise extremely rapid coalescence of gas bubbles.

Foams are thermodynamically unstable. A freshly prepared "wet" foam dissipates rapidly. Such a foam is of the spherical-bubble type [9] (Fig. 1 A), with individual bubbles having little influence upon one another. As a foam is dehydrated, the distance between bubbles progressively diminishes, leading ultimately to a "dry" polyhedral agglomerate of bubbles (Fig. 1 B). A metastable state can be established if equilibrium is reached among the various forces contributing to foam stabilization and destabilization [10].

Exceptionally regular polyhedral foam structures with a lifetime of several hours can be prepared if an appropriate system is thermostated and carefully protected from external influences [9], [11]. The physicochemical aspects of foam stabilization can be examined by preparing well-defined, isolated lamellae [10]. Nevertheless, a sound theoretical understanding of the various stabilization mechanisms has not yet been achieved.

2.2. Foam Formation

2.2.1. Surface Activity of Adsorbed Surfactants

The introduction and dispersion of a gaseous material under the surface of a foaming liquid (e.g., when air is brought into an aqueous surfactant solution) leads to the formation of rising bubbles. In the process, dissolved surfactant molecules diffuse out of the bulk phase toward the gas – liquid interfaces, to form reversibly adsorbed monolayers. Polar groups in the surfactant molecules remain directed toward the water, while hydrophobic chains extend into the air [12].

The spreading pressure π of an adsorbed surfactant increases to a limiting value as the surface concentration increases; this reduces the opposing surface tension of the initially pure liquid (γ_0) to a new value γ.

$$\pi = \gamma_0 - \gamma \tag{1}$$

The spreading pressure can be determined tensiometrically by the Wilhelmy method [13]. Because $d\pi = -d\gamma$, the spreading pressure characterizes the surface activity of a given surfactant or surfactant mixture at a particular concentration. At constant temperature, a dynamic

equilibrium is established between the surfactant dissolved in the bulk phase and the surfactant adsorbed at the boundary surface. Surface-active agents are repelled by the bulk phase because the van der Waals forces between water and the hydrophobic chains of the surfactant molecules are weaker than those between water molecules. At low concentrations, the amount of adsorbed surfactant Γ (surface concentration in moles per unit area) increases with increasing concentration c [14]. Simultaneously, the increasing spreading pressure π reduces the surface tension γ, as shown by Equation (1). For a nondissociating amphiphilic substance ($m = 1$), the following equation applies [15]:

$$G = -\frac{1}{mRT} \cdot \frac{\mathrm{d}\gamma}{\mathrm{dln}c} \tag{2}$$

Modified forms of this equation have been suggested [16] for ionic substances in which $1 < m \leq 2$. Equation (2) is known as the Gibbs adsorption equation; it describes an equilibrium situation and facilitates estimation of the surface area requirement per adsorbed molecule. Only at very low surface concentrations do hydrophobic groups lie flat on the surface, where they are free to rotate about their hydrophilic partners. A relatively low surfactant concentration often suffices to induce the formation of densely packed aggregates in which the hydrophobic chains are held erect.

Once the maximum spreading pressure has been reached, the adsorption capacity of the surface is fully utilized, so that the number of adsorbed molecules remains constant despite further increase in overall surfactant concentration. At this point, the two-dimensional structure is fully ordered. The critical micelle concentration (c_{M}), the concentration at which micelles begin to form, may be viewed as a measure of surface activity; above this value, the spreading pressure of a given pure surfactant is constant. Table 1 contains a selection of typical c_{M} values; these vary significantly as a function of the molecular structure of the surfactant. The effect of changes in the size of the hydrophobic group is illustrated in Figure 2. Nonionic ethoxylates with limited water solubility reach their maximum spreading pressure at extremely low volume concentrations. Concentration-dependent surface tension minima are commonly observed with commercial surfactants, but such minima appear to be caused by impurities. The time required to establish diffusion-controlled equilibrium increases markedly as the concentration differs from c_{M} [18] (Fig. 3).

Table 1. Critical micelle concentration c_{M} of surfactants at 25 °C

Surfactant	c_{M}, mol/L
$C_9H_{19}OSO_3Na$	59×10^{-3}
$C_{12}H_{25}OSO_3Na$	8.0×10^{-3}
$C_{16}H_{33}OSO_3Na$	0.38×10^{-3} (35 °C)
$C_{18}H_{37}OSO_3Na$	0.17×10^{-3} (50 °C)
$C_{12}H_{25}(OCH_2CH_2)_4OH$	4.3×10^{-5}
$C_{12}H_{25}(OCH_2CH_2)_8OH$	1.0×10^{-4}
$C_{12}H_{25}(OCH_2CH_2)_{12}OH$	1.4×10^{-4}
$C_{12}H_{25}N(CH_3)_3Cl$	1.8×10^{-2}
$C_{14}H_{29}N(CH_3)_3Cl$	5.0×10^{-3}
$C_{18}H_{37}N(CH_3)_3Cl$	3.5×10^{-4}

Surface tension vs. time curves for various concentrations of octylphenol dodecaglycol ether at 25 °C.

2.2.2. Methods of Foam Generation

Many techniques have been described for producing a foam [9], [19], but they fall into two main mechanistic categories.

Dispersion Methods. Mechanical action greatly increases the surface area that separates a liquid from a gas. The continuous phase may undergo extreme fragmentation, thereby establishing a foam with maximum homogeneity. Good results are often simply achieved in a long tube by establishing flow velocities in the turbulent range. In a commonly used procedure, the two phases are forced through a column tightly packed with glass beads or other appropriate material. Thin films of liquid form in the resulting narrow gaps, and these films are blown into bubbles by the passing gases. Foam generators and dispersion turbines operate in a similar fashion.

Condensation Methods. Foam generation methods based on condensation rely on spontaneous degassing of supersaturated, continuous liquid phases. The degassing may result from either pressure reduction or temperature increase. The most familiar example is the carbon dioxide foam that develops at the surface of carbonated soft drinks, beer, and sparkling wine. Although this method entails a minimum expenditure of effort, the associated costs often greatly exceed those of mechanical (dispersion) methods.

2.3. Foam Stability

The economic impact of practical foam problems is evident from the number of experimental and theoretical studies devoted to this subject [8], [20]. Unfortunately, most of the usual physicochemical measurement techniques are unsuitable for the direct study of such complicated agglomerates of draining gas bubbles in a moving, foaming liquid. More limited theories attempt to correlate foam stability with changes in a single dominant parameter. Several fundamental issues related to foam stability have been clarified by studies conducted on isolated foam lamellae. This is a legitimate approach, because foam degradation is a mechanical process consisting of the rupture of large numbers of individual lamellae [10].

2.3.1. Gibbs Film Elasticity and Marangoni Effect

Except in the case of pure liquids, foam bubbles and lamellae are stabilized relative to small changes in bubble size and lamellar thickness by two closely related mechanisms, the Gibbs film elasticity and the Marangoni effect.

Gibbs film elasticity E applies to extended lamellae with thicknesses several orders of magnitude smaller than their surface dimensions [21]. Film elasticity is defined as the quotient obtained by dividing an increment in the surface tension ($2\,\mathrm{d}\gamma$) by the corresponding increase in relative surface area of the film ($\mathrm{d}A/A$):

$$E = 2A \cdot \frac{\mathrm{d}\gamma}{\mathrm{d}A} = -2A \cdot \frac{\mathrm{d}\pi}{\mathrm{d}A} \tag{3}$$

Extension of a lamella results in a corresponding reduction in the equilibrium surface concentration of adsorbed surfactant molecules and thus in an increase in the surface tension γ, which acts as a restoring force (Fig. 4).

An additional stabilizing restorative force that diminishes with time also exists, this is known as the *Marangoni mechanism.* The time required for establishing the Gibbs adsorption equilibrium is determined by the diffusion-controlled transport of surfactant molecules out of the bulk phase.

The rapidly expanding, but still relatively thick lamellae characteristic of a low-viscosity, aqueous, spherical-bubble foam often exhibit surface depressions. These are caused by localized expansion and corresponding reductions in the spreading pressure. Adsorbed monolayers in undisturbed regions spread spontaneously into such depressions and compensate for the low surface concentration [22], [23]. Furthermore, solvated hydrophilic groups of spreading surface-active agents aid in the transport of interlamellar liquid from nearby layers, which helps compensate for the destabilizing effect of local dilution [24]. Both mechanisms are depicted schematically in Figure 4.

2.3.2. Rheological Aspects of Foam Stability

Foams tend to lose their interlamellar liquid under the influence of gravitational forces. As the

Figure 4. Schematic representation of the Gibbs and Marangoni foam-stabilization mechanisms

foam lamellae become thinner, their fragility increases. Thus, any factor causing resistance to flow should contribute to stabilization. Additionally, low-viscosity foams often exhibit yield points with important consequences from the standpoint of applications, as in the case of shaving cream [11].

Viscosity of the Interlamellar Liquid. An increase in viscosity diminishes the rate of escape of interlamellar liquid, thereby increasing foam stability and height [9], [18]. At the same time, however, high viscosity can also inhibit the process of foam formation.

Surface Shear Viscosity. Whereas three-dimensional rheology is the factor defining the dynamic viscosity of a bulk phase, the two-dimensional surface viscosity γ_s is responsible for the velocity gradient between parallel linear elements at a sheared surface [25]. Experimental determination of this parameter presents certain difficulties.

A modified couette system [26] is normally employed for measurements on non-Newtonian systems. The sample is placed in a rotating cup. An inverted bowl-shaped sensor is allowed to make concentric contact with the rotating liquid surface, thereby permitting accurate determination of the corresponding torque.

Absolute values can be determined even at elevated temperature, but their significance remains uncertain. Relative values are of more interest, particularly for surfactant mixtures, as are the significant increases in surface viscosity commonly observed with higher alcohols and other water-insoluble substances [27]. The expected proportionality between surface shear viscosity and foam stability has been confirmed to only a limited extent. Solutions of surface-active substances with a high surface shear viscosity do indeed exhibit significant foam stability, and foams in low-viscosity media subside rather rapidly; however, solutions with intermediate surface shear viscosities fail to yield satisfactory correlations.

Surface Dilatation Viscosity. Dilatation [28] and compression are modes of deformation that accompany pure shearing in certain types of flow. The surface dilatation viscosity K is determined with the aid of a modified film balance [29] by using the relationship

$$\Delta\gamma = K\frac{1}{A}\cdot\frac{\mathrm{d}A}{\mathrm{d}t} \tag{4}$$

The total surface of the surfactant solution under investigation is confined between two movable barriers whose position is varied such that the relative rate of expansion $d \ln A/dt$ remains constant. The resulting increase in surface tension $\Delta\gamma$ in the stationary zone between the barriers is measured tensiometrically by the Wilhelmy method [13].

Studies of the mechanism of lamellar rupturing suggest parallels between the stability of thin films and the corresponding surface dilatation viscosity [30].

2.3.3. Electrostatic Foam Stabilization

A fresh foam is a thermodynamically unstable system. However, thin lamellae can be transformed into a metastable state by electrostatic repulsion.

True Foam Lamellae. A solution that is supersaturated with a gas generally produces a spherical-bubble foam (see Fig. 1) [9], [11] containing considerable amounts of liquid. Progressive draining leads to rapid transformation of the spherical foam into a symmetrical polyhedral foam.

The lamellae within a polyhedral foam are separated from one another by surface regions exhibiting concave deformation as well as increased strength. These "plateau regions" [9], [10] have a destabilizing suction effect on the interlamellar liquid. An ideal unit cell of a uniform polyhedral foam resembles a regular pentagonal dodecahedron. However, true foams are ill-suited to the study of the opposing forces involved in progressive draining because of their instability.

Single Lamellae. Single lamellae can be withdrawn easily from a liquid with the aid of a glass frame [9], [10]. Unlike foams, they can be subjected to intensive investigation as long as they are protected from the effects of dust, evaporation, temperature change, and vibration. Lines of contact with the frame are characterized by plateau regions analogous to those encountered between the lamellae of a true foam.

Freshly drawn, vertically oriented lamellae are generally several micrometers thick. Liquid flows out of the center of such a lamella under the combined influence of gravity and the suction effect of plateau regions. A lamella stretched to a thickness between roughly 1000 and 100 nm displays a characteristic pattern of interference colors [9]. As soon as the lamellar thickness falls significantly below the wavelength of visible light, a "black film" results; which is so designated because of complete interference between incident and reflected light. Depending on a variety of factors, including the composition of the solution, lamellar shrinkage ceases at a thickness between 60 and 10 nm. The existence of such metastable black films implies that mechanical equilibrium is achieved between attractive and repulsive forces.

Figure 5. Force equilibria resulting in metastable lamellae [10]
A) Potential energy curves showing van der Waals attraction V_A, charge repulsion V_R, and the resultant energy V as a function of thickness d of the lamella
B) Disjoining pressure $p = -\delta v/\delta d$

A potential energy curve [10] can be used to illustrate the combined effects of repulsion caused by identically charged diffuse double layers adsorbed on the two faces of a surfactant film and the concurrent attraction due to van der Waals forces. Such a curve generally displays two minima (Fig. 5). Differentiation of the curve with respect to distance yields the *disjoining pressure* per unit area, a force which compensates in the metastable state (at equilibrium thickness d_0) for the destructive effect of suction.

The lamellar thickness corresponding to a black film represents the shallow secondary minimum on the potential energy curve. Conclusions derived from theoretical considerations can be largely confirmed at low salt concentrations [31], [32]. Thus, for a given disjoining pressure, the thickness of a metastable film decreases with increasing concentration of electrolytes (Fig. 6).

At higher electrolyte concentration, film thicknesses approach a limiting value of ca. 12 nm, a result which is essentially independent of the suction effect and may be due to additional separating forces of steric origin.

Metastable lamellae often transform themselves into "type II black films" with a thickness of only ca. 5 nm [10], [33]. These extremely thin "sandwich structures" probably consist of two surfactant films separated by a thin layer of water of hydration. They are thought to occupy the primary minimum in the potential energy diagram.

Figure 6. Disjoining pressure in a solution of sodium oleate (10^{-3} mol/L) at various sodium chloride concentrations

2.3.4. Mechanism of Lamellar Rupture

The surfaces of foam lamellae are under constant stress due to surface tension, a spontaneous force that tends to minimize surface extension. However, no direct relationship has ever been demonstrated between surface tension and foam stability. Rupture of the lamellae cannot, therefore, be regarded as a simple matter of overcoming some critical tear resistance; rather, it appears to be due to statistical fluctuations in lamellar thickness [34]. Reducing the thickness below a certain critical value ensures that the energy criteria for destabilization are met. Countless local instabilities can be expected to arise under practical working conditions as a result of vibration, temperature gradients, evaporation, and dust. Small particles of hydrophobic solids and liquids are particularly disruptive.

Lamellae containing relatively weak surface-active agents (alcohols or short-chain fatty acids) tend to decompose at an early stage of solvent exclusion and, therefore, never profit from the stabilization associated with thin black films. Instead, the concentration-dependent maxima observed for low-stability foams are attributed to the stabilizing effect of the Gibbs film elasticity (see Section 2.3.1) [35]. Lamellae associated with powerful surfactants rarely show such concentration-dependent maxima. Although the Gibbs stabilizing mechanism is inoperative, progressive thinning of the lamellae often terminates in a metastable black film rather than film rupture.

Many water-soluble polymers (e.g., gelatin and cellulose ethers) show very limited surface activity but nevertheless possess significant foam – stabilization power. The reasons for this are of rheological and especially steric origin. The most familiar example is the stabilization of beer foam by adsorbed protein – polysaccharide complexes.

2.4. Foam Inhibition and Destruction

A variety of chemical, biological, and technical processes are severely hindered by foam formation. Foams are controlled by chemical (Section 2.4.1), thermal, or mechanical (Section 2.4.2) means. In practical applications, foam inhibition, which aims to inhibit foam formation

in liquids, is distinguished from destruction of foams that have already formed. Thermal foam destruction primarily promotes bursting of enlarged gas bubbles and accelerates the destabilizing drainage of interlamellar liquids. However, this approach is often rather ineffective, and undesirable deterioration of the product is usually unavoidable.

Figure 7. Effect of a spontaneously spreading oil on lamellar thickness (Marangoni mechanism)

2.4.1. Chemical Foam Inhibition and Destruction

Effective foam inhibitors and defoaming agents often spread spontaneously over liquid surfaces. Earlier studies [36] assumed the existence of a causal relationship between this characteristic and foam destruction, but more recent findings [37] demonstrate frequent deviations from any such correlation. A foam inhibitor may be introduced in either dispersed (e.g., oils or pigments) or molecular form. The principal mechanism of action of oils appears to involve local displacement of the adsorption film containing the foaming agent. Thus, spontaneous spreading is not a precondition for effectiveness. What matters is that the surface-active component in the foaming agent should not be adsorptively incorporated into the oil – water boundary surface. The stabilizing film is, therefore, perforated; the lamellae become seriously deformed; and the interfacial surface energy of the moistened portion of the oil droplet approaches a maximum. Intensive investigation of pure sodium dodecyl sulfate and a range of purified liquid foam inhibitors provides support for this mechanism [37].

Another approach attempts to explain the mechanisms and energetics of foam destruction as consequences of two consecutive spreading phenomena. Thus, if drifting oil particles within the bulk phase are to be effective on the surface of a foaming liquid, two fundamental energy criteria must be fulfilled [8]:

1) Hydrophobic materials, rising because of their buoyancy, must spontaneously penetrate the liquid surface and form droplets. In the process, an aqueous film is replaced by an oil – gas surface. This step is characterized by a negative spreading coefficient S_1, which implies a positive "entering" coefficient.
2) Floating oil droplets must then distribute themselves spontaneously over the lamellae that are to be destroyed ($S_2 > 0$). This second condition is best fulfilled by foam inhibitors whose surface and interfacial tensions are both low.

However, hydrophobic agents characterized by these two criteria (i.e., $S_1 < 0$ and $S_2 > 0$) often prove to be rather poor foam inhibitors or combatants. In particular, silicone oils are ineffective unless they have been "activated" with highly dispersed particles of hydrophobic solids [38].

Particles of hydrophobic silica alone have a destructive effect on polyhedral foams, although they show no tendency to inhibit the formation of wet spherical-bubble foams [38]. On the basis of numerous investigations [39], this activity is now assumed to be a consequence of the free hydrophobic surfaces becoming hydrophilic due to adsorbed surfactants. Silicone oils spread in most media and protect the surface of hydrophobic silica particles, thus they transport active silica to the breaking foam bubbles.

The converse of the Marangoni effect also has a destabilizing effect [10], [24] because it leads to the removal of interlamellar liquid (Fig. 7).

The foam-destroying properties of dispersed, hydrophobic solid particles (e.g., Teflon, silanized silica, solidified paraffins, or sulfur) can also be explained in another way [40]: as the particles penetrate an expanding liquid lamella, they contribute to its rupture by

markedly increasing the interfacial tension. This phenomenon can be viewed as a displacement of the aqueous phase resulting from a dewetting tension (cf. the condition $S_1 < 0$ in [8]).

Soap mixtures with a broad range of chain lengths (C_{12-22}) are often used in detergents based on alkylbenzenesulfonates and fatty alcohol polyglycol ethers [41], [42]. The foam-inhibiting action is due to calcium salts formed in situ (see Section 3.6). Therefore, builders must not completely remove the calcium ions.

2.4.2. Mechanical Defoaming

Mechanical defoaming is used when chemical foam inhibitors or defoamers might impair process or product quality [43]. Foam lamellae can be subjected to high shear forces with the aid of centrifuges, injectors and ejectors, and especially, rotating disks. The dominant foam-breaking mechanism here involves the rupture of individual lamellae, which becomes possible above a specific minimum shear velocity [44]. Optimization of this approach is complex [43–45].

3. Antifoaming Agent Composition

Traditionally, antifoaming agents were often single-component liquid systems or homogeneous solutions derived from vegetable oils or their constituent glyceride oils and fatty acids. Other useful materials included mineral oils and their derivatives [46], [47]. However, more complex formulations were also known, including aqueous sols derived from plant phosphatides [48], as well as other water-soluble or water-emulsifiable preparations [49].

Modern antifoaming agents (also called defoamers) are formulated to meet more diverse demands, including optimal effectiveness, easy application in an industrial context, convenient dosage, low volatility, and safety from both toxicological and ecological standpoints.

Most defoamers are composites rather than simple substances. Several groups can be distinguished:

1) Liquid single-component systems or homogeneous solutions
2) Dispersions of hydrophobic solids in a carrier oil
3) Aqueous or water-containing emulsions or suspension
4) Solid defoamer formulations

The functional components of a foam inhibitor can be divided into four categories:

1) Carrier oils
2) Active ingredients
3) Amphiphilic substances
4) Coupling and stabilizing agents

Foam-inhibiting emulsions contain water, which serves as the continuous phase [50]. Solid foam inhibitors are free-flowing powders in which the foam-inhibiting ingredients, as well as any emulsifying or dispersing agents, are bound adsorptively to an inorganic sorbent such as calcium silicate [51] or sodium triphosphate [52], or to a polymeric organic matrix such as methyl cellulose [53]. Particulate solid antifoaming ingredients suitable for incorporation into detergent powder compositions comprise a core that consists of an oily, solid, or gel-like carrier material. The core supports the antifoaming substances and is surrounded by a coating which is disrupted on contact with water to release the antifoaming substances [54].

3.1. Carrier Oils

The most important carrier oils are water-insoluble paraffinic and naphthenic mineral oils, together with vegetable oils such as tall oil [*8000-26-4*], castor oil [*8001-79-4*], soybean oil [*8001-22-7*], or peanut oil [*8002-03-7*]. These oils themselves have foam-control capability. Useful agents for prolonging antifoam effectiveness, which to some extent also show synergistic activity, include residues from the oxo alcohol synthesis, alkylbenzenes, and crude oils from the low-temperature carbonization of brown coal or other bituminous materials.

3.2. Silicone Oils and Silicone Foam Inhibitors

Silicone oils are particularly effective antifoaming agents because of their low surface tension, thermal stability, chemical inertness, and

total water insolubility [55], [56]. One of the largest applications for silicone oils is their use as antifoaming agents in the petroleum industry, particularly in gas – oil separation [57]. By far the most important silicone oils are the dimethylpolysiloxanes [*63148-62-9*], in which chain ends are saturated with trimethylsilyl groups. The number of siloxane units present ranges typically from 2 to 2000.

Dimethylpolysiloxanes by themselves show little foam-inhibiting activity with respect to aqueous surfactant solutions. Most silicone defoamers are in fact not pure silicone oils, but rather silicone formulations supplemented with finely divided hydrophobic solid particles. These particles presumably confer the actual foam-inhibiting properties, while the silicone oil acts as a hydrophobic carrier oil that offers unusually good spreading properties [58].

Silicone foam inhibitors are supplied in the form of anhydrous dispersions of pyrogenic or hydrophobized silica [*7631-86-9*] in silicone oil. Such mixtures are oily and cloudy. In some cases they have the consistency of a paste, but the most commonly used foam inhibitors for aqueous systems are 5 – 50 % emulsions. Silicone antifoaming agent are directed toward suppressing undesirable side effects silicone antifoaming agents such as the formation of "fish eyes" in surface coatings, investigators have studied the effect of introducing organic residues into the polymeric siloxane matrix [59–61]. Other goals have included the development of foam inhibitors containing only traces of silicone oil, as well as silicone antifoams based on hydrocarbon oils [62]. Certain polyether modifications of poly(methylsiloxanes) have achieved importance as foam stabilizers and cell regulators in polyether urethane foams (→ Polyurethanes).

3.3. Hydrophobic Silica

The development of hydrophobic silica [63] can be regarded as one of the most important innovations in the field of foam-control agents. Several methods have been perfected for conferring hydrophobic properties on this normally hydrophilic material [64], the most important of which are

1) spraying the silica with silicone oil and tempering at 250 – 350 °C,
2) treatment with organosilicon halide vapors in an autoclave, and
3) dispersing the silica in a silicone oil at elevated temperature and recovery of the solid by centrifugation.

Hydrophobic silica can also be produced by reacting silicia hydrogel with alcohol [65], [66], fatty amines, or wax. Amorphous, precipitated silica (particle size 1 – 2 μm) is the most suitable starting material for foam-inhibiting agents from the standpoint of both cost and performance.

3.4. Hydrophobic Fat Derivatives and Waxes

Hydrophobic fats and waxes include the following materials:

1) fatty acid esters of monofunctional and polyfunctional alcohols;
2) fatty acid amides and sulfonamides;
3) paraffinic hydrocarbon waxes [*8002-74-2*], ozokerite [*8001-75-0*], and montan wax [*8002-53-7*];
4) phosphoric acid mono-, di-, and triesters of short- and long-chain fatty alcohols (for the triesters, even tributyl phosphate [*126-73-8*] and tributoxyethyl phosphate [*78-51-3*] have foam-inhibiting properties [67]);
5) short- and long-chain natural or synthetic fatty alcohols [68], [69];
6) water-insoluble soaps of long-chain fatty acids, including aluminum stearate [*637-12-7*], calcium stearate [*1592-23-0*], and calcium behenate [*3578-72-1*] [70];
7) perfluorinated fatty alcohols [71].

3.5. Water-Insoluble Polymers

A number of polymeric substances have been reported to have antifoaming properties, including low molecular mass, fatty acid modified alkyd resins; low molecular mass novolaks; copolymers of vinyl acetate and long-chain maleic and fumaric acid diesters; and methyl methacrylate – vinylpyrrolidone copolymers. Other relevant polymeric materials include poly(propylene glycols) and high molecular mass propylene oxide adducts to glycerol

[*56-81-5*], trimethylolpropane (1,1,1-tris(hydroxymethyl)propane) [*77-99-6*], pentaerythritol [*115-77-5*], triethanolamine [*102-71-6*], dipentaerythritol [*126-58-9*], or polyglycerol [*25618-55-7*] [72–74].

Addition products of butylene oxide or long-chain α-epoxides with polyvalent alcohols show the same effects as propylene oxide polymers [75], [76].

3.6. Amphiphilic Components

The category of amphiphilic compounds includes antifoam components with varying water solubility whose foam-inhibiting effects are due to a variety of mechanisms. Examples include sodium oleate [*143-19-1*] and the hardened fish fatty acid soaps used as foam regulators in detergents [41], [42]. The activity of the latter depends on in situ formation of calcium salts, which restricts their application to water that has not been demineralized.

Some amphiphilic substances are water soluble at low temperature but flocculate upon warming beyond a particular point called the cloud point. Above the cloud point, these surface-active materials act as foam inhibitors. Their foam-breaking effectiveness reaches an optimum at the cloud point itself. Examples of this type are nonionic surfactants such as modestly ethoxylated fatty alcohols, fatty acids, rosin acids, fatty amines, and alkylphenol derivatives with HLB (hydrophilic – lipophilic balance) values < 10. (For further explanation of HLB values, see → Emulsions, Chap. 9.2.) However, the effectiveness of this group of amphiphilic substances can be increased markedly if the free, primary hydroxyl groups of the polyglycol ether portions are blocked through esterification or ether formation with a hydrophobic residue.

Silicone surfactants can also be classified as amphiphilic substances. Silicone surfactants are silicone oils to which polyether groups have been chemically bonded. Introduction of polyether residues increases the hydrophilic character of a siloxane; as a result, it is no longer totally water insoluble and, instead, possesses a cloud point [77].

3.7. Emulsifiers

Emulsifiers assure rapid distribution of active ingredients throughout an aqueous phase (→ Emulsions). Those surfactants already enumerated in the amphiphilic category fulfill this role to some extent, although more strongly hydrophilic, nonionic surfactants with an HLB value > 10 are also employed (e.g., ethoxylated sorbitan esters).

3.8. Coupling Agents

Coupling agents increase the mutual tolerance of the various components of a foam inhibitor and prevent gel formation or sedimentation during long-term storage at fluctuating temperatures. Most of these materials are glycols, low molecular mass alcohols, or other ingredients known as solubilizers such as naphthalenesulfonate [*1321-69-3*] or *p*-toluenesulfonate [*657-84-1*].

4. Mechanical Means of Combating Foam

Foam problems can often be prevented or at least minimized by proper design of production facilities and careful adjustment of operating conditions. Examples include reduction of stirring rates, avoidance of vigorous boiling or sudden evacuation, and elimination of rough surfaces. Foam formation can also be reduced by careful control of venting operations, and by diminishing surface areas and the corresponding potential for uptake of air (e.g., by selecting tall vessels of limited diameter). The proper arrangement of heating devices can also have a beneficial effect, as can the choice of reactor construction materials. Thus, the presence of highly conductive materials in the region above the fill level of a reactor vessel can result in more rapid dissipation of foams with low stability.

Foam can sometimes be countered by spraying with finely divided water [78], introducing air (perhaps supplemented by carbon dioxide), use of a spark discharge [79] or balancing electrical charge [80]. Other mechanical approaches to dealing with foam include the removal of gases or gas-laden liquids by means of

a porous filter. This method is particularly applicable to fermentation processes and, under appropriate conditions, to the monomer-stripping operation of vinyl chloride used in the manufacture of poly(vinyl chloride) [81]. Modern computer technology has created new means of optimizing the rate at which the defoamer is supplied to the processing vessel [82].

5. Foam Problems in Specific Applications

5.1. Detergents

See →Laundry Detergents, Chap. 3.4.3. and [83].

5.2. Food and Beverage Industries

5.2.1. Cleansing and Disinfecting

Any surface that comes in contact with food or beverages during their manufacture, processing, or transport must be cleaned and disinfected at regular intervals. Because the affected industries (e.g., breweries, soft drink manufacturers, dairies, meat packers, the sugar and preserves industries) are confronted with very different problems of residue removal, a wide range of processes, cleansing agents, and disinfectants is required.

The ever-increasing role of mechanization and automation in industry has focused increased attention on potential foam problems. In particular, inconvenient foam formation must be anticipated in all of the following activities:

1) CIP ("cleaning in place") cleansing and disinfecting of tanks, if the active solutions are to be recovered and stored for reuse;
2) cleansing and disinfecting drums, containers, milk collectors, and other vessels if active solution is sprayed over the contaminated surfaces;
3) cleansing of returnable bottles, regardless of whether the automatic bottle-cleaning assembly utilizes immersion or spray technology; and
4) lubrication of bottle transport lines.

5.2.1.1. Tank Cleansing Based on the Cleaning-in-Place (CIP) Method

The CIP technique involves application of a recirculating cleansing or disinfecting solution onto the walls of a soiled tank by means of spray heads or targeted nozzles. Generally, the process is conducted at low pressure. Recovered cleansing solution is led into storage tanks to permit its reuse (Fig. 8).

Foam may cause air to be drawn into the circulating pumps, leave residues that are difficult to remove, or result in solution losses due to reservoir overflow. Residues that can produce foaming in the tanks include

1) proteins and fats (dairy industry);
2) proteins, polysaccharides, tannin or polyphenols, hop resins, and bittering agents (breweries); and
3) pectin, cell components, ethereal oils, and polysaccharides (vegetable and fruit juice processors).

Components of the cleansing or disinfecting agent itself may also present problems. These include nonionic, anionic, and cationic surfactants (e.g., quaternary ammonium compounds).

5.2.1.2. Cleansing of Returnable Bottles

A distinction is generally made between two fundamental types of bottle washers: those that utilize separate soakers (soaking baths) and those that combine soaking with spraying (Fig. 9).

Machines of the latter type are subject to foam problems both when the bottles are initially flooded with cleansing solution and later during spray cleaning. Foam arises as a result of the following contaminants.

1) soaps and surfactants originating in lubricants applied to the conveyor belt;
2) cellulose, sizing, surfactants, dyes, and pigments derived from bottle labels;
3) dextrin, casein, and vegetable gum, as well as synthetic glue, again from bottle labels; and

Figure 8. Cleaning-in-place (CIP) system for cleansing and disinfecting tanks

4) sugar, protein, and fat residues from the original beverages.

Intensive foaming in a bottle-cleaning line can result in overflow of the cleansing baths and can hinder the discharge of bottle labels. The labels tend to float in or on the foam. They gradually disintegrate and may eventually clog the spray nozzles. Foam also causes the recirculating pumps to draw a mixture of detergent solution and air, which in turn reduces the effectiveness of the bottle-flooding operation. Label fragments carried into the rinse baths can cause further clogging, and bottles may exit the machine contaminated with cleansing solution.

The most important characteristic of a foam inhibitor intended for use in a bottle-washing system is that it be stable to alkali. In some countries, including the Federal Republic of Germany, such agents must also be biodegradable (to the extent of 80 %, according to the German surfactant law). The latter requirement has been addressed in 1987 by the introduction of nonionic surfactants bearing specially designed protective end groups [84].

5.2.2. Food Processing

5.2.2.1. Sugar

Modern methods for processing sugar beets are fully mechanized and automated (→ Sugar).

The raw beets are first washed and chopped. The sugar is then extracted with hot water in extracting towers. The crude extract, which also contains nonsugar components of the beets, is treated first with limewater and then with carbon dioxide. The "lime sludge" includes most of the nonsugar components and is removed by filtration. The filtrate is subjected to multistage evaporation–ultimately under vacuum–leaving a supersaturated crystalline broth, the massecuite. Sugar is finally separated by centrifugation from the residual syrup, known as molasses.

More or less intensive foam formation is observed in each of the above steps [125]. The foam is attributed to the numerous nonsugar materials present, such as cellulose, lignin, protein, vegetable bases (betaine and choline), and especially, saponin.

Foam controllers employed in the beet-washing process are likely to appear in wastewater; therefore, biodegradability is an important prerequisite. Because sugar is intended for human consumption and trace amounts of antifoaming agents may be present in the finished product, various legal and health issues are involved (see Chap. 7) [126]. Furthermore, steam-volatile components must be avoided during the evaporation and boiling steps, as must any material that might leave deposits which would diminish the effectiveness of the heat exchangers. Foam-control agents must also not inhibit the ion-exchange resins commonly employed to remove residual hardness from the dilute syrup. Finally, antifoaming agents must not affect subsequent use of the molasses in yeast production (see below).

5.2.2.2. Yeast

Baker's yeast is prepared commercially in massive (up to 200 000-L) fermentation tanks. The most commonly employed nutrient is the molasses obtained as a byproduct of sugar refining.

A large amount of air is required to ensure rapid multiplication of yeast cells; it is generally introduced through a series of tiny nozzles. After 12 – 14 h, the yeast is ready for harvesting. It is removed from the exhausted growth medium, reduced to the proper moisture content by means of a rotary filter, and pressed into tablets for final distribution.

The initial stage of yeast culture is an anaerobic process that is rarely subject to disruptive foam formation; by contrast, fermentation is aerobic, and is generally accompanied by extensive foaming. Foam suppressants are necessary to prevent overflow from the fermentor [127]. This heavy foaming is due mainly to residual nonsugar beet constituents that accompany the raw molasses (see Section 5.2.2.1).

In modern yeast production facilities, foam suppressants are introduced by means of automatic electrode-activated devices. The chemical defoaming preparation chosen must not interfere with the transport of oxygen because yeast growth would then suffer [128, 129]. In addition, the absence of detrimental effects on the final yeast cubes, such as premature softening or liquefaction must be ensured [130].

5.2.2.3. Potatoes

Whether the product is potato chips, French fries, mashed potatoes, or potato starch, potato processing is always beset by foam formation. A wash bath is always employed, and foaming can lead to serious processing difficulties. Starch manufacture, in particular, is plagued by intensive foaming in the potato juice, the starch slurry, and the processing water, caused by proteins and other nitrogenous compounds found in potatoes. Starch foam is very stable and difficult to counter. Mechanical methods of foam control have such limited effectiveness that the addition of foam-control agents may be regarded as the most practical and universally applicable solution [131].

5.3. Metal Treatment

5.3.1. Foam Problems Associated with Cooling Lubricants

Cooling lubricants mixed with water are used frequently in the metal-working industry in conjunction with operations that involve the removal of shavings or turnings (e.g., drilling, turning, milling, or grinding) as well as in such processes as wire drawing, rolling, and deep drawing.

Cooling lubricants are concentrates based on mineral oils and emulsifiers. The user dilutes

these with water to the desired concentration. Certain applications require the use of oil-free, transparent solutions. Both emulsifiers and corrosion inhibitors can induce foam formation, which in turn diminishes the filterability and cooling capacity of the lubricant and may lead to overflow. Foam behavior is, therefore, an important consideration in the selection of emulsifiers and other components for a cooling lubricant concentrate. However, considerations related to emulsion stability often so limit the choice that the only way of avoiding foam problems is to incorporate additional foam inhibiting agents.

A widely accepted approach utilizes calcium soaps as foam inhibitors. These are formed when the soaps present in the cooling lubricant concentrate react with hardening agents in the water used to dilute the concentrate. The calcium soaps are produced as a finely divided suspension of insoluble particles. The amount and type of soap must be adjusted to ensure an appropriate amount of residue and the correct particle size and to avoid disruptive buildup of sediment.

Cooling lubricants normally have a working lifetime of weeks or even months. As a result, external influences can alter their foam behavior and may require the addition of other foam inhibitors based on wax dispersions or silicone oil. However, these materials cling to metal surfaces, which can lead to irregularities in subsequent surface treatment. Their application must therefore be kept to a minimum and should preferably be continuous rather than on an as-needed basis.

5.3.2. Foam in Alkaline Cleansing Solutions

Alkaline cleansing agents are used primarily for difficult industrial cleaning tasks such as the removal of large amounts of oil, fat, or pigments. They are also employed in the final preparation of metallic surfaces prior to finishing. The combined action of the builders, the surfactants, and various additives removes pigments, metal shavings, metallic soaps, graphite, fats, and oils and helps in dispersing and emulsifying soil particles in the wash liquor. Such agents are widely employed in repair shops, enameling, galvanizing, electroplating, and sheet steel manufacture.

The major constituents of alkaline cleansing agents used in the metals industry are builders and surfactants. Builders are generally hydroxides or inorganic salts, such as silicates, phosphates, borates, or carbonates of sodium or potassium. The surfactants include anionic materials such as alkylbenzenesulfonates, and/or nonionic substances. Such products are often supplemented with other substances (e.g., chelating agents, corrosion inhibitors) in order to meet the needs of a particular application.

In many cases, foaming can be controlled by *cloud point adjustment.* The cloud point is defined as that temperature at which a second phase, enriched in wetting agent, forms; it is recognized by the onset of cloudiness. The foaming tendency decreases rapidly above the cloud point, but cleaning capacity also diminishes. For this reason, the cloud point should be set slightly below the expected application temperature. However, the fact that the cloud point decreases with increasing salt concentration and thus with increasing total concentration of the cleansing agent must also be taken into consideration. Careful choice of nonionic surfactants with various HLB values, perhaps in combination with appropriate concentrations of one or more anionic surfactants, ensures that a specific cloud point will be obtained at the dilution employed. If properly employed, cleansing solutions whose cloud point has been correctly set, are free of foaming problems even when large amounts of air are introduced, as in spray applications.

If the surfactant concentration is not constant, e.g., due to contamination by extraneous surface-active substances, foam control by cloud point adjustment is no longer possible.

Extraneous surface-active substances may be introduced into a cleansing bath directly in the form of soil on the objects being washed or indirectly as a result of chemical reactions with the alkaline solution. Relevant soils include nonionic emulsifiers as well as fatty acids and other long-chain carboxylic acids present either as anionic emulsifiers or because of their effective lubricating properties. Carboxylic acid esters, which are often included in lubricating agents as high pressure (HP) additives (→ Lubricants and Related Products), are saponified in the alkaline cleansing solution to alcohols and high-foaming soaps. The rate of hydrolysis increases with increasing alkalinity, temperature, and concentration of cleansing agent as well as with rising emulsification potential. An example of the

problem is the cleansing with orthosilicate solution of cold-rolled black plate contaminated with palm oil.

In this case, introduction of specific foam-control agents on an as-needed basis may be advantageous. Foams due to soap can be controlled by soluble calcium salts, perhaps in the form of hard water added to make up for evaporative losses. Substances belonging to the category of ethylene oxide – propylene oxide block polymers [*9003-11-6*] are also commonly employed. Silicone oils are inappropriate for applications involving the cleaning of metals because they are likely to interfere with subsequent surface treatments.

5.3.3. Foam Control in Neutral Cleansers

Neutral cleansers are liquid industrial cleansers that provide temporary corrosion protection. Their basic chemical constituents are nonionic and cationic surfactants, as well as organic corrosion inhibitors. Neutral cleansers are used preferably in automatic spray washers at temperatures between 5 and 90 °C to clean iron or steel, aluminum, nonferrous metal, and plastic parts after cutting or noncutting working [85]. The aqueous solutions have a pH of ca. 9. Foam produced by vigorous mechanical action during spraying can be controlled by cloud point adjustment (see Section 5.3.2) of the nonionic surfactants; foam-controlling nonionics based on mixed ethers are now preferred for both ecological and toxicological reasons [84]. The cationic surfactants present in neutral cleansers also inhibit the formation of foams caused by extraneous anionic surfactants during spraying and thus permit recycling of the cleansing solution [86], [87].

5.4. Polymer Industry

Foam problems are common in the production of plastics, synthetic rubber, and polymer dispersions. Foaming may accompany not only the actual polymerization step but also the recovery of unreacted monomer and the packaging, transfer, and transport of aqueous dispersions or latices.

Foam problems during polymerization are particularly common when heat generated by the reaction is removed by refluxing low-boiling monomers, e.g., in the preparation of poly(vinyl acetate) or poly(vinyl chloride).

Emulsion (E) polymerizations have a greater tendency to foam than suspension or dispersion polymerizations. Weakly foaming anionic emulsifiers [88], [89], oligomeric carboxylates [90], and low foaming nonionic coemulsifiers [91] have all been proposed as agents for the prevention of foaming during emulsion polymerization. The correct choice of the primary emulsifier for the polymerization is also important because substances in this category vary widely in their foaming tendencies (Fig. 10).

Figure 10. Foaming behavior of anionic primary emulsifiers at 25 °C
a) Nonylphenol + 4 EO sulfate; b) Lauryl alcohol + 4 EO sulfate; c) Lauryl alcohol + 50 EO sulfate; d) Lauryl alcohol + 30 EO sulfate; e) Nonylphenol + 10 EO sulfate; f) Lauryl alcohol + 10 EO sulfate; g) Nonylphenol + 25 EO sulfate
EO = ethylene oxide.

Differences are also observed, in various suspension (S) polymerizations, with regard to foaming. For example, S-PVC charges containing poly(vinyl alcohol) as a protective colloid foam more readily than those in which cellulose ethers are used to stabilize the suspension. Foam is commonly combated at this stage by spraying the stirring vortex with antifoaming agents, but mechanical means are also employed, including spraying with water [92] or bursting the bubbles with a propeller [93].

In the synthesis of both poly(vinyl chloride) and synthetic rubber, the polymerization reaction is usually terminated before complete conversion which necessitates the recovery of un-

reacted monomer. In the case of synthetic rubber, the latex is freed from monomeric butadiene in large decompression vessels. Less volatile monomers such as styrene are removed by passing the latex through a column against a flow of rising steam.

A significant improvement was introduced in 1965 by BASF, which resulted in simpler, quicker, more efficient monomer recovery. In the BASF process, steam is passed at high velocity through the boiling polymer dispersion to produce a steam – dispersion – foam mixture that carries residual monomer with it. This mixture is then subjected to rapid decrease in pressure, during which the foam is destroyed. Steam is separated from the broken dispersion foam, and the latter is returned to the boiling polymer dispersion [94].

In the case of S-PVC, demonomerization [95] involves either the use of a multicompartment vessel equipped for countercurrent vapor removal [96] or countercurrent vapor removal through a continuously operating column [97]. For E-PVC, the method of choice is spraying in conjunction with a pressure gradient [98].

Foaming during monomer removal [99] is caused by surface-active protective colloids or emulsifiers. Foam control by purely mechanical means may suffice, but in most cases antifoaming agents are employed. Among the criteria used in choosing them are

1) effectiveness with respect to the nonionic protective colloids in the case of suspension polymerization;
2) effectiveness with respect to the anionic emulsifiers in the case of emulsion polymerization;
3) stability to acidic or alkaline conditions, depending on the method of PVC manufacture employed; and
4) long-term stability and activity consistent with multistep, continuous stripping operations.

Silicone antifoaming agents are generally avoided, particularly for poly(vinyl chloride) destined to be made into film or where foam might be expected to play a role in further processing.

The choice of possible antifoaming agents for use in the manufacture of poly(vinyl chloride) or for the preparation of polymer dispersions is often severely restricted by the fact that proposed ingredients may have to be approved by a national health agency such as the FDA (United States) or the Bundesgesundheitsamt (Federal Republic of Germany).

5.5. Paint and Coating Industry

In the paint industry, foam formation can interfere with various processing steps. In addition, inadequate foam control (or use of the wrong foam-controlling agent) can negatively influence the decorative value or surface-protective function of the finished product. Foam problems may be encountered during pigment dispersion, introduction and mixing of the pigment dispersion and binder, transfer of the finished paint into cans, or final application–whether by brush, sprayer, or dipping [100].

Paint formulations are prepared in some types of stirring apparatus by blending a mixture of pigments and fillers with water to form a paste. The water is supplemented with dispersing agents [101], wetting agents, or a suitable combination of the two.

Dispersion is most commonly effected today with the aid of a dissolver. The shear forces required, coupled with the effects of dispersing and wetting agents, result in formation of a prodigious amount of foam, which is further stabilized by the presence of thickening agents such as poly(vinyl alcohol) or hydroxyethyl cellulose. The nature of the pigments themselves is also a factor. Finely divided pigment particles (e.g., carbon black or phthalocyanine blue) tend to promote foam formation. Foam control is complicated further by the presence of iron oxide pigments, which have a tendency to adsorb and thus neutralize the effect of antifoaming agents.

In the paint industry, the antifoaming agent should be tailored to the specific application at hand [102], [103]. Screening tests should be performed to verify that a particular antifoaming agent is effective and application tests should be conducted in its presence [104].

A pigment dispersion containing the defoamer is applied with a sponge roller to a piece of molded fiberboard, whose smooth side has been sealed with the appropriate polymer dispersion. After the paint has dried, the appear-

ance of the coating is compared with samples comprising a graduated test scale (Fig. 11). A given antifoaming agent must be evaluated further for microfoaming, a particularly frequent problem with modern aqueous coatings. This is done by examining paint applied to a glass plate and exposed to incident light from two neon tubes [103].

Air introduced into a nonaqueous paint produces a spherical rather than a polyhedral foam (see Chap. 2). If insufficient time is available for air to escape during the drying process, cavities or pinholes may form during baking: e.g., rapid evaporation of solvent near the surface may result in the surface becoming closed, and bubbles entrapped in the lower layers may burst at a later stage in baking when the coating has become so viscous it cannot flow into developing vacancies. The most effective remedy is incorporation of high-boiling solvents or solvent mixtures.

The decisive factor, with respect to foam behavior and foam control for water-borne coatings (e.g., acid-functional acrylic polymers cross-linked with melamine) is the bulk viscosity of the mixture, which is often dictated by the proposed application conditions [105]. The increasing use of such coatings in the automotive industry has resulted in concern about foaming during the removal of paint residues. These residues (oversprays) are withdrawn from the spray booth through a circulating water system. Special coagulating agents are added to cause pigment agglomeration, after which the pigment is precipitated with the aid of a flocculant (Fig. 12). Surface-active substances tend to cause foam formation in the constantly recirculated water; this, in turn, may clog the circulating system and reduce the effectiveness of the precipitating steps. In severe cases, the coating process itself can be affected [106]. Special silicone-free antifoaming agents have been developed exclusively for this application.

5.6. Construction Industry

Since 1945, polymer dispersions have played a rapidly increasing role in the construction industry. The plasticizing influence of such dispersions permits a reduction in the amount of water required to make cement and similar materials workable. More important, however, the addition of polymer dispersions to mortar leads to greater tensile strength in bending, and plaster containing both polymers and mineral binders has better adhesion and less tendency to crack.

Increased amounts of emulsifiers and dispersing agents are required to stabilize polymer dispersions. These increase the risk that foam produced during mixing of the latex and the cement or mortar will result in undesirable entrapment of air bubbles, thereby reducing the ultimate stability of the solidified mass. Antifoaming agents utilized in this context must be stable to alkali and must not have an adverse effect on key properties relevant to the construction trade (e.g., nonflammability requirements) [107].

In some cases, powder defoamers are added directly to the cement or mortar mix [108], [109]; silicone antifoaming agents are also used [110]. Appropriate low-foaming dispersions utilizing antifoaming agents with good long-term stability could be offered by latex manufacturers themselves, thereby obviating the need for subsequent introduction of foam-control substances [111].

5.7. Adhesives Industry

Most industrial adhesives are applied mechanically. The entrapment of tiny air bubbles during application may change the material flow characteristics and result in an uneven or damaged adhesive layer along with a corresponding reduction in the tensile strength of the adhesive bond.

The foaming tendency and the extent of foam formation depend upon the nature of the binding agents and other components added to the formulation. Natural binders such as starch, soy protein, cellulose ether, and natural rubber either are inherently surface-active materials or contain impurities that are surface active, such as saponin (in starch) or lipoproteins (in natural rubber latex). Synthetic binders contain surface-active stabilizers. Soaps based on fatty acids or rosin acids are present in synthetic rubber latex; poly(vinyl acetate) dispersions contain hydroxyethyl cellulose or poly(vinyl alcohol); synthetic anionic or nonionic emulsifiers are found in acrylate and methacrylate polymers. Foam stability is enhanced by thickeners such as methyl

Figure 11. Comparison scale for evaluating the effects of foaming during application of an emulsion paint

cellulose or polyacrylate, which increase the viscosity of the mixture and thus inhibit the degradation of foam once it has been produced.

Antifoaming agents for adhesive applications must be chosen for their suitability with respect to the particular surface-active agents in question. Adhesives that may come in contact with food or the human body must meet relevant legal requirements (Chap. 7).

Under certain conditions, foam can be turned to technical and economic advantage. For example, controlled foam formation in the Nordson Foam Melt process [112] results in hot melts with prolonged open time as well as improved flow and filling characteristics and more rapid setting. The amount of adhesive required is also reduced.

5.8. Textile Industry

Most chemical processes associated with the textile industry occur at the fiber surface and in aqueous medium. Surfactants improve the wettability of fiber surfaces, help displace adsorbed air, aid in the emulsification and dispersion of textile auxiliaries, and facilitate removal of soil from fabric surfaces (→ Textile Auxiliaries).

The increased rate of machine operation and material transport in modern textile mills implies an enormous expenditure of mechanical energy. Foam formation must be anticipated in any operation in which air is permitted to enter the treatment baths. The detrimental effects of foam may be qualitative, as in the case of "spoiled" goods (fabrics showing irregularities in surface treatment, undesirable depositions, spotting), or quantitative in the sense of requiring more complicated machinery or reduction in output.

Three general approaches have been taken to solving the textile industry's foam problems:

1) Mechanical – technological solutions
2) Introduction of foam inhibitors
3) Use of low-foaming surfactants in the formulation of textile auxiliaries

In most cases, a combination of measures is required.

Pretreatment and dyeing are the most important and critical textile processing steps with respect to foam control, but other stages in the process (e.g., fiber manufacture or fabric sizing, imprinting, and finishing) also present foam problems.

5.8.1. Pretreatment

The processing of cotton and spun rayon involves alkali treatment and mercerization; fabric is subjected to various concentrations of sodium hydroxide in the presence of wetting agents that are usually anionic in nature. Especially with the "dry-in-wet" process, but also with "wet-in-wet" technology, some introduction of air is inevitable. The preferred method of foam control relies on phosphate esters of alcohols containing four to eight carbon atoms (e.g., tributyl phosphate). These esters are stable in solutions containing high concentrations of alkali and electrolytes.

Other pretreatment steps conducted in a strongly alkaline medium rich in powerful anionic and nonionic surfactants include boiling off (alkali extraction of cotton) and bleaching, particularly when hydrogen peroxide is used as the bleach. Both processes are amenable to either continuous or batchwise implementation.

Batch treatment is increasingly carried out in jet or overflow systems. If the processing equipment is not completely filled with liquor, a more or less intensive–but, in any event, disruptive–foaming can be anticipated as a result of the high flow rates and rapid material transport. Foam at this stage interferes with homogeneous treatment of the fabric, which has a tendency to float. In addition, mixtures of surfactants and antifoaming agents tend to separate as a result of the high shear forces present in the circulating pumps. Foam residues (including silicone defoamers) may also remain on the fabric and cause spotting. Therefore, low-foaming wetting agents should be selected from the outset, and silicone-containing foam control agents must be avoided. The usual alternatives are formulations based on tributyl phosphate.

Continuous processing in an open-width unit also presents severe foam problems, because surfactant may be present in concentrations up to ten times that required for a batch process. Rotor jet agitation of the treatment bath and spray jet equipment aggravate the situation.

Mixed ether formulations [84] represent one modern solution to such foam problems, especially in bleach baths. Their foam-inhibiting power is particularly noteworthy at bleach-bath temperatures above the cloud point of the additives.

The use of low-foaming wetting agents can largely obviate the need for supplementary foam control agents in a peroxide bleaching bath. Moreover, these surfactants are biodegradable. Hydroxyalkane ether sulfonates prepared by SO_3 sulfonation of mixed ethers of unsaturated fatty alcohols are especially suitable [113].

5.8.2. Dyeing

Dyeworks are the largest consumers of foam-control agents in the textile industry. Because water is the only feasible solvent for dyeing and all water-insoluble dyes must be introduced as dispersions, dyeing involves many surface-active auxiliaries such as wetting agents, dye dispersants, and leveling agents.

The foam problems associated with dyeing are comparable to those encountered during pretreatment (Section 5.8.1), in part because much of the processing machinery (both batch and continuous) is similar. The same applies to dye posttreatments, which include steps designed to improve fastness, as well as various finishing operations using fabric softeners (usually cationic)

or other processing aids (e.g., finishes for improving sewability).

Dyers often utilize special silicone antifoaming agents, but preparations devoid of silicones are also used.

5.8.3. Foam Application of Textile Auxiliaries

Even though foam is generally regarded as a disruptive influence in textile manufacture, it can also serve a useful function, as in the case of foam application technology [114], [115], particularly because this opens the way to energy-efficient drying. Foams also play a structural role in certain finished products such as carpet backing, and foam is useful in situations calling for application of a substance to only one side of a fabric.

Foam technology has become an established part of such operations as rotary screen printing, fabric coating, bonding of nonwoven fabrics, backing (upholstery fabrics), and certain types of dyeing.

5.9. Leather Industry

Almost every stage of leather processing–from rawhide to consumer product–involves contact or treatment of the leather with surface-active compounds. During processing of the hides in the beam house, and subsequent tanning, dyeing, and fat-liquoring, inconvenient foam is countered largely with the aid of silicone foam-control agents. In many cases, the necessary treatment aids contain appropriate foam-regulating additives.

The problems faced during leather finishing are considerably more complex. Many finishing agents contain surfactants or are applied in the form of emulsions (e.g., casein solutions, silicone emulsion for use as a feel agent, wax emulsions, nitrocellulose emulsions). Pigmented dispersions contain wetting or dispersing agents, and aqueous acrylic resins are polymer emulsions that incorporate anionic or cationic emulsifiers. Foam formation during finishing and coating can lead to serious process disruption. The choice of a suitable antifoaming agent is often difficult because it must be both highly effective and, at the same time, compatible with other aspects of the process; it must in no way lower the quality of the final finish [116].

5.10. Pulp and Paper Industry

The paper industry is one of the major consumers of foam-control agents. Foam is a problem at every stage from pulp and paper fabrication through coating and printing, as well as in the reprocessing of wastepaper and the treatment of wastewater.

5.10.1. Pulping

The alkaline conditions required by the sulfate pulping process result not only in the solubilization of lignin but also in the production of soap. The soap originates from resin acids found in the resin ducts of coniferous trees and from fats and resins located in the parenchymal cells of deciduous trees. The soap is responsible for the generation of considerable amounts of foam. Depending on their degree of dispersion, colloidal and finely dispersed cellulose particles and fibrils can stabilize this foam. The resulting fiber suspension is washed in multistage brown-stock washers at a temperature of more than 82 °C and a pH of ca. 12, to remove most of the residual cooking liquor. The antifoaming agents must therefore be effective at high temperature and alkali-stable [117].

In addition to the sulfate process, sulfite pulping is still of some importance, particularly in Europe. In this process, lignin is solubilized and extracted from the wood in the form of ligninsulfonate. Sulfonation is performed using a hot aqueous solution of sulfites or hydrosulfites, sometimes in the presence of excess sulfur dioxide. Sulfite pulping liquor is acidic, and foam generation is due to the presence of ligninsulfonates and other surface-active materials containing sulfonate groups. The resulting demands on any potential antifoaming agent are, therefore, different from those in sulfate pulping [118].

Foam controllers for pulping must be effective against large-scale foam production. In addition, they must be capable of dissipating gas entrapped in small bubbles stabilized by minute

cellulose fibers. This gas consists of air as well as carbon dioxide arising from fermentation of raw materials or chemical reactions associated with hard water. Insufficient attention to this problem results in a pulping mixture that is difficult to filter, and the washed pulp is likely to contain undesirable tall oil residues.

5.10.2. Pulping Liquor Disposal

Both economic and environmental considerations require that spent liquor from the pulping operation be subjected to further, extensive treatment. Evaporative measures are complicated by foam due to the presence of dissolved soaps derived from fatty acids and abietates. Such foams can be controlled with the aid of mixtures of organic solvents and nonionic surfactant [119]. Suitable wastewater defoamers can also be obtained by reacting fatty acid esters, fatty alcohols, or paraffinic hydrocarbons with liquid or gaseous sulfur dioxide [120].

5.10.3. Air Content of Pulp Suspensions

A common problem in paper manufacture is entrapment of air as a result of the turbulence associated with rapidly moving machinery. Dispersed air can lead to tiny bubbles in the paper or to foam on the surface, thus reducing the rate of subsequent moisture removal and lowering product quality. The seriousness of the problem can be reduced by incorporating degassing devices but high-speed processes require supplementary chemical measures to further suppress foaming and minimize air content.

Most of the standard wetting agents are unsuitable for degassing purposes. The most effective air release agents are slightly water-soluble, nonionic surfactants such as water-in-oil emulsifiers. Ethoxylation products based on fatty alcohols, fatty acids, or ricinoleic acid play a particularly important role [121].

5.10.4. Conversion to Paper

Foam formation in the paper-making machine results from mechanically introduced air that interacts with surface-active compounds present in added sizing agents. Foam of this type interferes with the formation of a closed fiber structure. It also inhibits drying and causes irregularities in the paper surface. Choice of an appropriate foam-control agent is difficult because of adverse potential effects on the sizing process, contamination of the rollers, or further disruption of the integrity of the paper surface [122].

5.10.5. Paper Coating

The binders utilized in paper coating are water soluble starch, cellulose ethers, and casein or aqueous polymer dispersions based on copolymers of styrene – butadiene and acrylic esters. The synthetic binders are particularly likely to cause foam problems and surface disturbances. Air cannot be excluded to a sufficient degree from the coating materials themselves; hence, the addition of chemical foam-control agents is common practice [123]. These differ from the antifoam preparations employed in paper making and must conform to the synthetic emulsions used in coating materials.

Figure 13. Deinking process
Flotation causes dislodged ink pigments to be collected by air bubbles and removed along with the foam.

5.10.6. Waste Paper Deinking

Air is deliberately introduced during the flotation deinking of paper waste. This induces the formation of air bubbles at the surface of the printing ink pigments and reduces the effective density of the pigment particles. The particles rise to the surface thus separating the ink from the fibers (Fig. 13). The solid particles in the foam are separated from the aqueous phase by centrifugation or passage through a belt filter press [124].

5.11. Phosphoric Acid Manufacture

The phosphoric acid used in fertilizers is produced primarily by the wet process in which phosphate-containing minerals are reacted with aqueous sulfuric acid. The accompanying release of carbon dioxide and silicon tetrafluoride leads to vigorous foaming, especially at the onset of the reaction. Foam may also be encountered during subsequent vacuum evaporation of the crude phosphoric acid. These foams are stabilized by insufficiently wetted, finely divided crystallites of the water-insoluble mineral gypsum. Powerful wetting agents provide a reliable solution to the problem. Anionic surfactants such as oleic acid, dioctyl sulfosuccinate, sulfonated tall oil, or mineral oil are especially useful [132]; they are often introduced in combination with fatty alcohols and nonionic surfactants (e.g., fatty alcohol and fatty acid ethoxylates). A mixture of a high molecular mass, water-insoluble, polyacrylamide flocculating agent and sulfonated tall oil fatty acids is particularly effective [133].

5.12. Wastewater Treatment

Wastewater entering a treatment plant is first freed of voluminous material by filtration through a coarse sieve. It is then passed through a series of channels designed to reduce its velocity so that sand and gravel settle and are left behind. The water then enters a large sedimentation container, from which the sludge is transferred into ponds or digesters.

The water emerging from a sedimentation unit still contains dissolved solids and colloidal particles derived from organic matter, and it may be subjected to further treatment by activated sludge. This requires that the liquid be brought into intimate contact with air, either by mechanical action or by using finely divided airstreams. Aeration is a rather violent process and may lead to serious foam problems.

Although foam is particularly undesirable at the stage of activated sludge treatment, it can also be encountered elsewhere in the process. In addition, foam buildup may occur in large bodies of water or streams. Such foam not only interferes with the control, observation, and management of water, but also reduces the effectiveness of water purification measures.

As the surface activity of the impurities present increases, so do the tendency toward foam formation and the stability of the resulting foam. Materials of low surface activity lead to formation of unstable foams, which dissipate without the need for special intervention.

Analysis of the water emerging from the treatment plant does not permit accurate determination of the cause of a particular foam episode. For this reason, foam-control agents are usually selected on the basis of laboratory experiments and field trials. Nonetheless, certain criteria can be applied in their selection. One of the criteria is the pH of the wastewater: an antifoaming agent that is effective only in alkaline medium is clearly of little interest if neutral water is to be treated. Second, an antifoaming agent that is to be introduced at the biological stage of wastewater treatment must not have a detrimental effect on the microorganisms responsible for purification. In addition, some antifoaming agents may have a positive or a negative effect on the flocculating process. Any foam control measures taken must be compatible with the particular flocculation procedure employed.

6. Testing Methods

Because of the variety of industrial processes in which foam formation occurs and the various effects of defoamers, three fundamental types of foam-related tests are used:

1) Tests to assess the foam-producing potential of a particular substance
2) Tests of the effectiveness of a given antifoaming agent
3) Tests to establish the effect of a particular antifoaming agent on the final product

Numerous standard test procedures have been developed. Usually, the foams are generated by one of the following techniques:

1) The test solution is confined within a cylindrical container and agitated with a perforated plate (DIN 53 902, p. 1).
2) A defined volume of the test solution is poured from a specific height onto the surface of the same liquid ("free-fall circulating

method" or Ross – Miles test; DIN 53 902, p. 2).

3) Air is introduced directly into a test liquid, through a capillary (DIN 51 381), a standardized paper disk (DIN 515 666), or an appropriate sintered-glass device (ASTM D 892-72).

In these procedures, either the time required to obtain a particular quantity of foam or the volume of foam produced under test conditions is measured. Additional information can be derived from measurement of the time required to dissipate the foam.

Additional methods for establishing the foaming capacity of surfactants, particularly those relevant to the detergent industry, are given in [12].

As many of the factors influencing foam formation as possible must be considered. Test conditions should be analogous to those expected in the field, especially with respect to temperature and the means of air introduction. Standard test conditions often have to be modified to ensure their relevance to a specific situation.

7. Legal Aspects

Numerous restrictions apply to the use of antifoaming agents in the manufacture of foods and other commercial products. Some take the form of prohibitive laws and ordinances, while others involve lists of permitted agents (positive lists). A multitude of regulations exist worldwide; the discussion that follows is confined largely to the Federal Republic of Germany and the United States.

Paragraph 11 of the German Food and Consumer Products Law of 15 August 1974 explicitly prohibits the use of additives in food products [134]. However, certain exceptions are permitted if the additives are removed completely prior to distribution or if they are removed as completely as possible and, at the same time, confer no undesirable taste or odor and pose no health risk. Examples of the unavoidable introduction of antifoaming agents are provided by the yeast, sugar, and potato chip industries.

The use of plastics in the context of food products is covered by recommendations of the Plastics Commission (Kunststoff-Kommission) of the Federal Health Office (Bundesgesundheitsamt, BGA), which must in turn comply with the Food and Consumer Products Law [134]. For example, recommendation XIV of the Bundesgesundheitsamt (Synthetic Polymer Dispersions) contains under the heading "Processing Aids" a section entitled "Antifoaming Agents."

The U.S. Code of Federal Regulations gives a list of permitted substances, along with their chemical constitutions and allowable levels in food products (Title 21, "Food and Drugs," § 173.340, Defoaming agents). Other relevant material includes defoaming agents used in coatings (§ 176.200) and defoaming agents used in the manufacture of paper and paperboard (§ 176.210).

Defoamers are also mentioned in § 240.1051 (Materials authorized for the treatment of wine). Those defoamers listed in § 176.200 are implicitly allowed under § 177.1200 (Cellophane) and § 177.1400 (Water-insoluble hydroxyethyl cellulose film), and the list in § 176.210 also applies to § 175.105 (Adhesives).

Under the auspices of the Joint Expert Committee on Food Additives of the FAO – WHO, efforts are being made to establish international guidelines. The use of foam-control additives in food products is thus subject to constant critical review with respect to both the nature and the amount of substances used.

8. Economic Aspects

Foam problems arising in industrial processes are a matter of immediate concern, because they can rapidly lead to serious economic consequences. For example, an automatic papermaking machine or bottle-washing unit may have to be shut down, and inadequate degreasing during metal treatment or surface irregularities resulting from foam or from use of the wrong antifoaming agent might lead to defective products. On the other hand, a certain amount of foaming may be permitted in a production line operating at less than full capacity to avoid the extra cost of foam-control measures.

These factors introduce a large measure of uncertainty into predictions of the market for antifoaming agents. The demand for foam-control agents in the United States has been estimated

at 136 000 t/a, and world demand is thought to be almost twice this value.

Table 2. Summary of commercial antifoam products

Trade name	Firm	Application
Afranil	BASF, FRG	paper industry
Agitan	Münzing Chemie GmbH, FRG	wide assortment for various industrial applications
Alkaterge	Angus Chemical Co., USA	fermentation
Antimussol	Sandoz, Switzerland	textile and paper industries, cutting oils
Antispumin	Chemische Fabrik Stockhausen, FRG	paper, textile, and sugar industries
Bayer-Entschäumer	Bayer, FRG	silicone defoamers
Baysilone-Entschäumer	Bayer, FRG	silicone defoamers
Bevaloid defoamers	Bevaloid Ltd., UK	wide assortment for various industrial applications
Byk	Byk – Mallinckrodt, FRG	paint and coating industry
Contraspum	Zschimmer & Schwarz, FRG	wide assortment for various industrial applications
Degressal	BASF, FRG	detergent and cleansing industry
Dehydran	Henkel KGaA, FRG	wide assortment for various industrial applications
Dow – Corning Antifoam	Dow – Corning, USA	silicone defoamers
Etingal	BASF, FRG	paper and textile industries
Foamkill	Lehmann & Voss, FRG	wide assortment for various industrial applications
Foammaster	Henkel KGaA, FRG	wide assortment for various industrial applications
Fumexol	Ciba – Geigy, Switzerland	textile industry
General Electric Silicone AF	General Electric, USA	silicone defoamers
Mazu	Mazer Chemicals, USA	wide assortment for various industrial applications
Nopco	Henkel KGaA, FRG	wide assortment for various industrial applications
Plurafac	BASF, FRG	low-foaming nonionic surfactants
Polymekon	T. Goldschmidt, FRG	paint and pigment industries, silicone defoamers
Ralulac	Raschig GmbH, FRG	emulsion paints, leather and textile industries
Repriman	Henkel KGaA, FRG	paper industry
Respumin	Bayer, FRG	silicone defoamers

Because of the multitude of industries serviced, the marketing of antifoaming agents necessitates a high level of specialization. Moreover, provision of an adequate level of customer service is also necessary. Suppliers of antifoaming agents differ markedly in their orientation and in their range of product lines. Thus, some suppliers specialize in specific types of material (e.g., silicone antifoaming agents), while others address the concerns of particular industries (e.g., suppliers to the textile industry). Table 2 lists commercial antifoaming products.

Table 2. (Continued)

Sentry Simethicone	Union Carbide, USA	pharmaceutical, cosmetic, and food processing industries
SAG-Silicone-Antifoams	Union Carbide, USA	silicone defoamers
Surfinol	Air Products, USA	low-foaming wetting agents
Tego-Entschäumer	T. Goldschmidt, FRG	paint and pigment industry, silicone defoamers
Tegosipon	T. Goldschmidt, FRG	paint and pigment industry, silicone defoamers
Texadril	Henkel KGaA, FRG	low-foaming wetting agents
Troykyd	Troy Chemical Corp., USA	wide assortment for various industrial applications
Viscasil	General Electric, USA	silicone defoamers
Wacker-Silikon-Antischaummittel	Wacker, FRG	silicone defoamers

1. Introduction

Foods are mixtures of chemicals that are consumed by humans to satisfy their appetites for nourishment and pleasure. The nature and reactivity of the chemical constituents determine the properties of foods. The sensory properties, i.e., appearance, flavor, and texture, determine the acceptance of food and the pleasure derived from consuming it. Water-soluble components (salts, sugar, acids, and bitter substances) determine the taste, and volatile compounds determine the aroma. The texture is due to insoluble complexes or compounds such as proteins and polysaccharides; in some foods, lipids contribute to texture. Pigments are critical contributors to appearance. Most of the nutrients are provided by proteins, vitamins, and minerals, whereas carbohydrates and fats provide the energy. The ideal food should be both delicious and nutritious. Unfortunately, many nutritious foods are considered unappetizing by many people.

The following procedures or processes have been used to produce appealing, nutritious foods (for details, see → Foods, 2. Food Technology):

1) *mixing products,* e.g., fruit salads, vegetable salads, and fruit yogurts
2) *adding seasonings or other materials,* e.g., adding soy protein to sausage or smoking meats
3) *fractionating* to produce new products, e.g., separating milk to yield cream and skim milk

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a11_491

4) *homogenizing* to produce a more uniform product, e.g., peanut butter or milk
5) *fermenting* and *pickling* to produce new and more stable products, e.g., cheese manufacture
6) *enzymatic treatment,* e.g., enzymatic modification of starch to produce corn syrups of varying sweetness
7) *thermal processing* including cooking and baking, to destroy undesirable microbes, enzymes, and antinutrients such as trypsin inhibitors and enhance sensory appeal.

2. History of Food Production and Preservation

In the beginning, foods were selected from available natural products [1–8]. This led to the development of regional eating habits. The origin of modern economic plants was possibly as follows [1]:

Central Asia	apple, barley, broad bean, carrot, celery, cherry, cucumber, date, eggplant, lentil, lettuce, melon, mulberry, mustard, olive, onion, pea, pear, plum, pomegranate, quince, radish, rye, spinach, turnip, wheat
Mediterranean	artichoke, asparagus, cabbage, cauliflower, fig, horseradish, parsley, parsnip
Southeast Asia	banana, breadfruit, orange, peach, persimmon, rice, soybean, sugar cane, yam
Central or South America	avocado, cassava, corn, cranberry, kidney and lima bean, pineapple, potato, pumpkin, squash, sweet potato, tomato

At first, selection of food from the available supply was based primarily on sensory properties. By trial and error, people learned that some products satisfied their appetites while others adversely affected their health. The people who made the right choices lived to pass on the information to the next generation.

In the days when humans were merely hunters or gatherers of foods, the adequacy of diet depended on the types and quantity of available plants and animals. The need to develop methods for preserving food for use throughout the year became obvious. Concern over the quantity and quality of food increased as population increased. These food problems stimulated development of methods for producing and preserving foods (→ Foods, 2. Food Technology). The progression of civilization from the food gathering stage to the early food production era, i.e., from the Old Stone Age to 400 AD, is shown in Table 1.

In Germany, substantial increases in agricultural production occurred after the introduction of the iron plow in the 6th century, the horseshoe in the 9th century, and the horsecollar soon after. The threefold rotation system (one-third of the land remained fallow, summer crops were raised on another third, and winter crops on the other third) also increased production.

During the *Middle Ages* the variety of available foods increased as a result of increased traveling and trading. The discovery of America had a pronounced effect on the variety of food with the introduction of potatoes and corn, as well as other native American products, such as tomatoes, peanuts, lima beans, and turkeys.

The 16th century marked the beginning of the so-called *Golden Age of Science* [1], [6–10]. During this time, scholars investigated the nature and composition of foods. Some of the components discovered are listed in Table 2. These discoveries gave credibility to the scientific approach to biological problems and stimulated further research and technical developments (Table 3).

In the *last two centuries* considerable progress has been made in increasing the quantity and improving the quality of food [11], [12].

Food Quantity. Quantitative increases in the food supply have resulted from the following:

1) The use of better breeding practices and careful genetic selection, which led to the development of high yielding varieties of wheat and rice.
2) Replacing draft animals with mechanical power increased the acreage that could be farmed and released millions of hectares of land that had been devoted to raising feed for horses. However, mechanization of agriculture increased fossil fuel consumption.
3) Irrigation has converted vast areas from desert or semidesert to profitable food producing areas. Unfortunately, continuous irrigation has caused water logging and increased soil salinity.
4) The use of chemical fertilizers has created remarkable increases in production (Fertilizers). The gains have been partially offset by

Table 1. History of growing, processing, and preserving food [1]

Date (approximate) Period	Food	Farming–trading	Preserving–processing	Scientific–technological advances
Prior to 15 000 BC Paleolithic (second period of Stone Age)	eggs, fish, fruits, honey, insects, nuts, seeds, roots, small animals		drying, pounding, roasting	bags, baskets, clothes, language, "made" fire, painting, sculpture, stone and bone implements
15 000 BC Mesolithic (transitional period of Stone Age)	bigger selection of food, storing berries and wild fruits		boiling, drying fish, smoking, steaming, storing food	bow and arrow; dog, goat, reindeer, and sheep (domesticated); claycovered baskets
9000 BC Neolithic (last period of Stone Age) *villages*	domesticated animals, milk, butter, cheese, gruel, dates, olives, grapes, beer, vinegar, wine	cultivating cereals (seasonal) in permanent fields using hoes and hand plows, pruning	alcoholic fermenta-tion, adding acetic acid, salting, baking, making bread, sieving, pressing primitively, seasoning	pottery wheel; spinning; weaving; wood, flint, and bone sickles; saddle quern; mortar; fishing with hooks and nets
3500 BC Bronze *cities*	soybeans, figs, rice, olive oil, vegetables, lentils, cabbage, cucumbers, onions	irrigating, plowing with horses and oxen, much trading locally and externally	filtering, lactic acid fermentation, more types of flavoring, flotating, leavening bread, making sausage, frying, pressing (sophisticated and complex), clarifying	architecture, smelting, wheeled carts, ships, writing, bronze tools, mathematics, rotary millstones, bronze weapons, astronomy, shadoofs, medicine, chemistry
1500 BC Iron	artichokes, beans, fruits, lettuce, sauces, spices	trading by land and sea, using heavier plows	refinement of flavoring and cooking	pulleys, glass, improved and cheaper tools and weapons, currency
600 BC – 400 AD Roman	sugarcane, apples, asparagus, beets, oranges	using reaping machines, rotating legumes, using plows with wheels, trading extensively	food adulteration common	water mills, donkey mills, wooden cooperage

Table 2. Some components isolated from foods prior to 1800

Component	CAS registry number	Food	Investigator
Lactose	[*63-42-3*]	milk	F. Bartoletti (1586 – 1630)
Fructose	[*57-48-7*]	honey, raisins	J. R. Glauber (1604 – 1668)
Gluten	[*8002-80-0*]	flour	F. M. Grimaldi (1618 – 1663)
Tartar, ethanol	[*868-14-4*], [*64-17-5*]	wine	J. D. Portius (1636 – 1703)
Sucrose	[*57-50-1*]	beets	A. S. Marggraf (1709 – 1792)
Citric acid	[*77-92-9*]	lemon juice, gooseberries	C. W. Scheele (1742 – 1786)
Malic acid	[*6915-15-7*]	apples	
Glycerol	[*56-81-5*]	olive oil	

Table 3. Chronology of some developments in food technology

Date	Inventor	Process or product	Purpose
1679	Papin	digester	cooking in iron pot with clamped on lid
1809	N. Appert	appertization	cooking in sealed glass jars
1810	N. Appert	autoclave	cooking canned food under pressure
1830	A. Coffey	Coffey still	continuous distillation
1830	N. Rellieux	triple effect evaporator	energy efficient evaporation
1835	Sulzberger	roller milling	roller process for flour milling
1855	J. A. Just	roller dryer	energy-efficient drying
1856	G. Borden	evaporated milk	milk evaporated under vacuum and packed in hermetically sealed cans
1860	F. Carre	mechanical refrigerator	water–ammonia system for providing refrigeration
1865	L. Pasteur	heat treatment	initially to preserve wine, then used to destroy pathogens in grape juice and milk
1874	A. K. Shriver	retort	closed kettle using super-heated or live steam for canning
1877	G. de Laval	cream separator	rapid centrifugal separation of cream
1911	A. J. A. Ottesen	quick freezing process	minimizing adverse effects on food during freezing
1920	Kidd & West	controlled atmospheric storage	minimizing quality changes during storage of fruits
1931	C. Birdseye	multiple freezer	energy-efficient freezing
1945	E. W. Flosdorf	freeze-dryer	drying of frozen food under vacuum

the cost of the fertilizers in terms of dollars and expenditure of fossil fuel. In some cases the runoff of chemical fertilizers has polluted drinking water and increased the growth of algae in the streams, which has killed fish.

5) The use of pesticides has also contributed to the world food supply by eliminating pests that reduce yields or pests that consume harvested foods (Crop Protection). Because pesticides contribute to pollution and are hazardous to some species of animal life, alternative pest control methods have been and are being sought. Some success has been achieved in breeding disease-resistant varieties of plants and in developing biological methods, e.g., microbial parasites, that destroy the pests (Biological Control).
6) Reduction in postharvest losses has been achieved by using storage facilities and packages that protect the food from biological, chemical, and physical damage (Foods, 4. Packaging). In developing countries, postharvest losses can be as high as 50 % for some commodities [13].
7) Recovery of foods and ingredients from underutilized products. For example, recovery of proteins from whey and blood [14–17], underutilized meats from chicken [18], [19] and fish [20], [21].

Food Quality. Much of the progress in solving food quality problems can be attributed to basic scientific studies that have identified the causes for changes in quality, e.g., LOUIS PASTEUR's studies, which led to pasteurization (→ Foods, 2. Food Technology, Chap. 4.1.). In the process of studying the mechanism of thermal destruction of microbes, researchers noted that in some cases thermal processing also affected flavor, color, and texture [6], [7], [22–24]. Heating fluid dairy products produced cooked (custardlike) flavor, which was found to be due to the release of sulfhydryl groups from proteins [25]. More drastic heating of milk or other foods containing carbonyl and amino groups caused both flavor and color changes. In 1908, A. R. LING described this reaction, and in 1912 L. C. MAILLARD investigated the mechanism [26]. Direct heating of products with high sugar content produced both caramel color and flavor. Heating affected the texture of meat and eggs by altering the proteins. It was found that the activity of many endogenous food enzymes could be controlled by thermal processing [27], [28]. The importance and nature of enzymatic changes are discussed in Section 3.7 (→ Enzymes).

Scientific studies have shown that many changes in food quality are due to either oxidative or hydrolytic reactions, and therefore, controlling them is important [6], [7], [29–31]. *Oxidative changes* have been minimized by (1) storing food in a controlled atmosphere, (2) using packages that are impervious to oxygen, (3) inactivating oxidative enzymes, (4) avoiding contamination with catalytic metals, or (5) addition of antioxidants (→ Antioxidants; → Foods, 3. Food Additives, Chap. 3.2.). *Hydrolytic changes* have been inhibited by (1) inactivating hydrolytic enzymes, (2) maintaining the integrity of cell walls or membranes, which protect the substrate, or (3) adding inhibitors [32].

3. Components and Their Reactions

Foods range in complexity from a single compound (e.g., sugar) to multicomponent mixtures (e.g., meat). The properties of foods reflect the properties of the individual components and their interactions. *Food interactions* include all types of noncovalent (van der Waals, hydrogen, ionic, and hydrophobic) and covalent bonds. These interactions contribute to a variety of structural features such as cell walls, micelles, fat globules, fat globule membranes, three-dimensional gel structures, muscle fibers, and curds.

The *reactions of components* in foods are affected by pH, temperature, concentration of reactants, available water, catalysts, activators, and inhibitors. They may be catalyzed by light, enzymes, and nonenzymatic materials such as metals. Inhibitors can be substances that chelate metal catalysts or that interact with one of the reactants. Chelating agents can react with calcium or iron and thus reduce their nutritional availability. The nutritional quality of foods can also be reduced by oxidation of essential fatty acids or other nutrients, or by the interaction of proteins with tannins. The optimal sensory and nutritional properties can be obtained by controlling the reactions of the components.

3.1. Water

Occurrence. Water [*7732-18-5*] is one of the basic and most ubiquitous constituents of living organisms, [6], [7], [33–36]. The water content of raw fruits, vegetables, and meats exceeds 50 wt %, but the concentration in cereals, nuts and many processed foods is lower (→ Foods, 2. Food Technology, Chap. 2.).

Water exists naturally as an intracellular or extracellular component in plants and animal products. It is used as a solvent for sugars, salts, and acids in some foods, as a dispersing medium for hydrophilic macromolecular carbohydrates or proteins, and as a dispersed phase in emulsified products such as butter and margarine.

Properties. Compared to other substances with similar molecular masses, water is unique (→ Water). Its ability to engage in three-dimensional hydrogen bonding enables it to bond with organic molecules that contain nitrogen, oxygen, fluorine, or chlorine. The dissolution of sugar is because of bonding between water and the polar groups of the sugar. Dissolution of salts involves electrostatic forces between water and the positive ions which are greater than the attraction between ions.

Effect on Food. Water acts as a dispersing medium for amphipathic molecules, such as polar lipids, which have both hydrophilic and hydrophobic groups. The water associates with the hydrophilic moieties, such as phosphate groups, to "solubilize" the molecules. The amphipathic molecules form macromolecular aggregates, which are called micelles. Introducing hydrophobic substances, such as apolar groups of fatty acids, amino acids, and proteins, into water leads to an association of the apolar groups, i.e., hydrophobic interactions.

Water may be present in food as "free" water or "bound" water. *Free water* behaves like pure water, whereas the behavior of bound water is limited. *Bound water* has been defined as water that is not available as a solvent and does not freeze at − 40 °C, although some scientists have suggested other definitions. The term "water binding" has been defined as the tendency of water to associate, with various degrees of tenacity, to hydrophilic substances. "Water-holding capacity" has been used to describe the ability of a matrix of molecules to entrap a large amount of water in such a manner that exudation is prevented [7]. Although the entrapped water does not flow freely from the product, it behaves very much like pure water during processing. The water-holding capacity of meats and gels have a profound effect on rheological properties. The water-holding capacity of meats is affected by pH and salts, especially phosphates. A classification of water–protein thermodynamic associations is as follows [34]:

Structural water is water that is hydrogen-bonded to specific groups; it participates in stabilization of structure and is unavailable for chemical reaction.

Hydrophobic hydration water is structured cagelike water surrounding apolar residues; like structural water, it is very much involved in stabilizing protein structure.

Monolayer water is the first adsorbed water monolayer; it is hydrogen-bonded and is unavailable as solvent, but may be available for chemical reactions; ranges from 4 to 9 g/100 g protein.

Unfreezable water includes roughly all water (structural monolayer, and perhaps some adsorbed multilayer water) that does not freeze at normal temperature; amounts to 0.3 – 0.5 g/g of protein and corresponds to water up to $a_w = 0.9$; amount varies with polar amino acid content and includes some water available for chemical reactions.

Capillary water is water that is held physically in clefts or by surface forces in the protein molecule (e.g., water entrapped in gels or cheese curd); its physical properties are similar to those of bulk water.

Hydrodynamic hydration water "loosely" surrounds the protein and is transported with the protein during diffusion (centrifugation); it has properties typical of normal water.

Water Activity [6]. A complete discussion of water activity can be found under → Foods, 2. Food Technology, Chap. 1.4.

Perishability. A general correlation exists between the perishability of food and water content, but a better correlation exists between perishability and water activity (→ Foods, 2. Food Technology, Chap. 1.). Both enzymatic and

nonenzymatic reactions tend to increase as water activity increases. However, enzymatic reactions are less sensitive to water activity changes. Nonenzymatic browning reactions reach a maximum rate at $a_w \approx 0.80$. Lipid oxidation is inhibited by increasing water content. Under some conditions water may form a protective film around the fat. The destruction of vitamin C and chlorophyll increases rapidly as the water activity increases. The rate of vitamin B_1 destruction reaches a maximum at $a_w \approx 0.5$ [7].

Food Quality. A complete discussion of the effect of freezing the water in food has on food quality can be found under → Foods, 2. Food Technology, Chap. 3.2.

3.2. Proteins (→ Amino Acids; → Proteins);[6], [7], [29], [37–44]

Structure. Proteins are polymers composed of amino acids linked together by peptide bonds. Proteins constitute ca. 50 % of the dry matter of living cells and perform a vital role in the function and structure of the cells. Proteins containing only amino acids are called homoproteins, whereas those containing additional groups (i.e., prosthetic groups) are called heteroproteins. The heteroproteins include lipoproteins, glycoproteins, phosphoproteins, hemoproteins, metalloproteins, and nucleoproteins.

The complexity of proteins depends on the number and types of amino acids and other groups. The primary, secondary, and tertiary structures of proteins are discussed under → Proteins. The structural properties of some major food proteins are shown in Table 4.

Denaturation. The secondary and tertiary structures of proteins are fragile and, therefore, can be changed by a variety of treatments that do not cleave covalent bonds (with the exception of disulfide bonds). The term denaturation is applied to such processes. *Heating* is the most commonly used physical method for denaturing proteins. Most proteins are denatured or coagulated between 55 and 75 °C. The susceptibility of proteins to denaturation depends on the nature of the protein and environmental factors such as pH, water activity, ionic strength, and the types of ions present. The proteins of egg white are readily denatured by heat, whereas casein and gelatin are relatively resistant. This resistance is attributed to the presence of high amounts of proline and hydroxyproline and low levels of sulfur-containing amino acids. Thermal denaturation of proteins can result in the following:

1) inactivation of enzymes
2) destruction of microbes
3) detoxification of toxic proteins
4) increased protein digestibility
5) improved texture of protein-rich foods
6) increased exposure of hydrophilic groups

The exposure of hydrophobic groups can cause changes in water and flavor-binding capacity and in solubility.

Physical treatments other than heating can also cause protein denaturation or other protein alterations. *Freezing and low-temperature storage* can cause aggregation and precipitation of some proteins (e.g., gliadin, 11 S soy proteins, and some egg and milk proteins). Aggregation refers to clustering of protein molecules or particles. In food systems, aggregation usually involves hydrophobic forces, but other forces may be involved in some cases. Precipitation involves separation of the protein from the rest of the solution or suspension. In some cases aggregation leads to precipitation. After freezing, fish may become tough and rubbery and lose moisture as a result of protein destabilization. Some *mechanical treatments,* such as the rolling and kneading of bread, may denature proteins. *High hydrostatic pressure* may also have a denaturing effect. Ovalbumin and trypsin have been reported to be denatured at pressures of 50 and 60 kPa, respectively [7]. *Electromagnetic irradiation* can cause changes in the conformation of proteins. The extent of such changes depends on the wavelength and energy involved.

Proteins can also be denatured by *chemical reagents.* The structural stability of proteins is influenced by pH, with each protein having a characteristic stable range. Consequently, shifting the pH outside of this range with either acid or base denatures the protein. In some cases, native structure can be restored by readjusting the pH to within the stable range.

Alkaline-earth elements, such as calcium and magnesium, may react with proteins. Ions of copper, iron, mercury, and silver react even more

Table 4. Structural properties of some major food proteins [7]

readily, often forming stable complexes with thiol groups. Some of these ions become an integral part of protein molecules, micelles, or other molecular associations. Removal of ions by dialysis or chelating agents can reduce protein stability.

Organic solvents may denature proteins by altering the dielectric constant of the medium and, therefore, the electrostatic forces that contribute to protein stability. Urea and quinidine salts promote denaturation by disrupting hydrogen bonds. Nonpolar solvents can penetrate into hydrophobic regions, disrupting hydrophobic interactions and enhancing protein denaturation. Surface-active agents, such as sodium dodecylsulfate, also disrupt hydrophobic regions and promote the unfolding of native proteins. Unfolding can also be enhanced by anionic detergents. The conformation of proteins can be modified by reducing disulfide cross-links with reducing agents such as cysteine and ascorbic acid.

Maillard Reaction. The nonenzymic browning or Maillard reaction is one of the most important reactions in food. It involves reaction between the amino groups of proteins, peptides, or amino acids with reducing sugars and can produce either desirable or undesirable effects. The amino groups react with a glycosidic hydroxyl group to form an *N*-substituted glycosylamine. The glycosylamine undergoes an Amadori rearrangement to form an aldoseamine or ketoseamine. The aldoseamine could react with a second amino group to yield a diamino sugar, or the ketoseamine could react with a second aldose to form a diketoseamine. Both of these paths produce melanoidin pigments, which have pyrazine and imidazole rings in addition to hydroxymethyl furfural. The types of end products depend on the nature and quantity of the sugar and the molecules containing the amino groups. The browning reaction is affected by temperature, pH, moisture level, and the presence of oxygen, metals, phosphates, and inhibitors such as sulfur dioxide.

The impact of the browning reaction on flavor, color, and nutritive value depends on the type of reactants and end products. Desirable colors and flavors are produced during the broiling of meat or fish, baking of bread, or roasting of coffee. Frying potato chips containing high glucose levels can produce brown spots and some undesirable flavors. Undesirable flavors and colors develop during storage of dairy products that have been subjected to high heat, e.g., evaporated milk and ultrahigh-heat-treated milk. The color and flavor changes are usually accompanied by losses in nutritive values. Sugars destroy the nutritive value of lysine because they react readily with its ε-amino group. This loss can be significant because lysine is the limiting amino acid in many proteins (cf. essential amino acids). Other amino acids, especially the other basic amino acids, L-arginine and L-histidine, are also susceptible to degradation.

Degradation of amino acids via the Maillard reaction may occur before any visual browning. Furthermore, amino acid losses may result from the *Strecker degradation,* which does not produce browning. The Strecker degradation, which involves interaction of dicarbonyl compounds and amino acids, produces a variety of flavorful aldehydes and nitrogen-containing compounds such as pyrazines. These compounds contribute to the flavor of chocolate, honey, maple syrup, and bread [7].

Strong alkali treatment of proteins can induce changes that may result in reduction of their nutritive value [49]. This reduction may be due to the loss of limiting amino acids. The availability of some amino acids may be reduced by alkali-induced amino acid isomerization. Cystine can be converted to aminoacrylic acid (dehydroalanine), which can react with the amino group of lysine to form lysinoalanine. Under stronger alkaline conditions, arginine may be converted to ornithine and urea. Ornithine can then combine with dehydroalanine to yield ornithinoalanine. It has been postulated that lysinoalanine and ornithinoalanine may contribute to inter- or intramolecular cross-links, which reduce the accessibility of proteins to proteolytic enzymes. Although mild alkali treatments of proteins probably do not have a significant nutritional effect, processors should carefully control these treatments.

Lysinoalanine can produce toxic effects in rats, but these effects have not been observed in other experimental animals [7], [49].

Oxidation contributes to the loss of some amino acids. Methionine can react with lipid peroxides to yield methionine sulfoxide. Cysteine can be oxidized to cystine and then to alanine by

lipid free radicals. Light-induced oxidation of methionine produces methional and a mixture of sulfides, which imparts the so-called light-induced flavor to milk.

The physicochemical properties of proteins that affect their behavior in food systems during preparation, processing, storage, and handling are called *functional properties.* These properties and their role in food systems are listed in Table 5. Research on functional properties has been greatly stimulated by the use of proteins from plant sources such as soybeans. Modification of proteins by enzymatic, chemical [43], or texturization procedures [37], [42] are being used to improve protein functionality.

Table 5. Typical functional properties performed by functional proteins in food systems [40]

Functional property	Mode of action	Food system
Solubility	protein solvation	beverages
Water absorption and binding	hydrogen bonding of water; entrapment of water (no drip)	meat, sausages, breads, cakes
Viscosity	thickening; water binding	soups, gravies
Gelation	protein matrix formation and setting	meats, curds, cheese
Cohesion–adhesion	protein acts as adhesive material	meat, sausages, baked goods, pasta products
Elasticity	hydrophobic bonding in gluten; disulfide links in gels	meats, bakery
Emulsification	formation and stabilization of fat emulsions	sausages, bologna, soup, cakes
Fat absorption	binding of free fat	meats, sausages, doughnuts
Flavor binding	adsorption, entrapment, release	simulated meats, bakery, etc.
Foaming	form stable films to entrap gas	whipped toppings, chiffon desserts, angel cakes

Nutritive Value. The nutritive value of a protein depends on its amino acid content and its digestibility. The *essential amino acids* (i.e., those that must be supplied by the diet) are isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine for adults plus histidine for infants. A perfect protein must contain the proper concentrations of the essential amino acids, and they must be available (i.e., digestible). In general, animal proteins more nearly meet these criteria than plant proteins. Cereal proteins are low in lysine and some also lack tryptophan. Proteins from legumes often lack methionine, and oil seeds and nuts frequently lack both methionine and lysine. The amino acid deficiencies of individual proteins can be wholly or partially overcome by inclusion of another protein that has a complementary amino acid pattern. Cereal and legume proteins complement each other. Diets in which 30 – 40 % of the proteins come from animal sources usually contain a proper balance of amino acids.

The *availability of amino acids* depends on the ability of the digestive tract's proteases to digest the proteins. Poor digestibility may be due to several factors: (1) protein conformation; e.g., soluble globulins are more digestible than insoluble fibrous proteins; (2) presence of enzyme inhibitors, such as the trypsin inhibitors, in soybeans; (3) presence of substances that form indigestible complexes with proteins such as metals, nucleic acids, and tannins.

3.3. Lipids (→ Fats and Fatty Oils ; → Fatty Acids; → Fatty Alcohols), [6], [7], [29–31], [35]

Composition. Lipids include a variety of compounds that have been classified as follows [29, p. 140]:

1) *Simple lipids* (neutral lipids): esters of fatty acids with alcohols, e.g., fats and waxes
2) *Compound lipids:* compounds containing fatty acid esters plus other groups, e.g., phospholipids (phosphatides), cerebrosides (glycolipids), sphingolipids, and sulfolipids
3) *Derived lipids and lipid-soluble substances,* e.g., fatty acids, long-chain alcohols, sterols, hydrocarbons, carotenoids, and fat-soluble vitamins

Commercial fats and oils are mixtures of the three classes of lipids, with simple lipids (principally triglycerides) making up the major portion. Mixtures that appear solid are often called fats, whereas liquid mixtures are called oils. In this article, the term fat will be used to include both types.

Properties of the natural fats depend mainly on the fatty acid composition and the distribution of fatty acids in the glycerides. The fatty acid composition of a variety of fats and oils can

be found under → Fats and Fatty Oils. The differences in fatty acid composition partially explains the differences in melting points and melting point ranges. Butterfat, which has a large variety of fatty acids including several fatty acids with branched chains and odd-numbered carbon atoms, has a wide melting point range. Cocoa butter has a limited number of fatty acids and a narrow melting point range. Tallow with a relatively high concentration of long-chained saturated fatty acids has a high melting point, whereas the highly unsaturated safflower oil has a low melting point.

The distribution of fatty acids in the triglycerides of natural fats is shown in Table 6. Cocoa butter has very little trisaturated (GS_3) or triunsaturated (GU_3) types of triglycerides and is hard and brittle below the melting point, which makes it useful for chocolate and confectionery manufacture. The effects of the types of fatty acids and triglycerides on melting points are shown in Table 7.

Table 6. Triglyceride types and isomeric forms of natural fats [29]

	Types ∗, wt %				Isomers∗, wt %			
	GS_3	GS_2U	GSU_2	GU_3	SUS	SSU	USU	UUS
Pig fat	2.5	22.4	55.7	19.4	1.0	21.4	46.9	8.8
Peanut oil	0.1	9.9	42.5	47.5	9.3	0.6	0.7	41.8
Beef fat	12.6	43.7	35.3	8.4	30.6	13.1	3.4	31.9
Cocoa butter	7.1	67.5	23.3	2.1	65.0	2.5	0.2	23.1
Soybean oil	0	3.7	31.0	65.3	3.7	0	0	31.0

∗ G = Glyceride, S = saturated fatty acid, U = unsaturated fatty acid.

Table 7. Melting points of some triglycerides [6]

Triglyceride saturation	Fatty acids∗	*mp*, °C
Trisaturated	S–S–S	72
	P–P–P	65
	S–P–P	62
Disaturated	P–O–P	37
	O–P–P	34
	S–O–P	35
	S–P–O	39
	P–S–O	36
Diunsaturated	O–O–P	19
	O–O–S	23
Triunsaturated	O–O–O	5
	E–E–E	42
	L–L–L	− 10

∗ S = stearic; P = palmitic; O = oleic; E = elaidic; L = linoleic.

Solidified fats exhibit polymorphism; i.e., they can exist in different crystalline forms, depending on the modes of molecular packing in the crystal. Triglyceride may exist in three forms: α, β', and β, in order of increasing stability. The crystal form has a marked effect on the melting point. For example, the melting point of α, β', and β forms of tristearin are 54.7, 64.0, and 73.3 °C, respectively [6].

Chemical reactions of fats can have a significant impact on food quality. Hydrolysis of triglycerides, which releases glycerol and free fatty acids, can alter both flavor and texture. *Hydrolysis* of fats, such as coconut, palm kernel, and butterfat, which contain volatile, fatty acids (i.e., C_4–C_{10}), develops hydrolytic rancidity or lipolyzed flavor. This flavor is objectionable in fluid milk, but a low concentration is desirable in some cheeses. Extensive hydrolysis of any fat alters the texture because the melting point is changed. Hydrolysis rarely occurs in the absence of lipolytic enzymes. The rate of lipolysis depends on lipase activity and the availability of the substrate. In raw fluid dairy products, lipolysis can be a serious problem because these foods usually contain active lipase, and the substrate is available. Treatments that disrupt the fat globules increase substrate availability. Many psychotropic bacteria produce lipase, which may cause trouble during storage of foods.

Oxidation of fats contributes to development of undesirable flavor in foods. Fats with a high concentration of polyunsaturated fatty acids (Table 7) are very susceptible to oxidation, which leads to the production of a mixture of flavorful carbonyl compounds, mainly six- to ten-carbon aldehydes and ketones. Lipid oxidation is catalyzed by metals (e.g., copper and iron), ultraviolet light, and lipoxygenases, which occur in some plant sources. Metal-catalyzed oxidation can be inhibited by metal chelating agents such as citric acid and ethylenediaminetetraacetic acid (EDTA). The most commonly occurring natural antioxidants are the tocopherols, which inhibit the oxidative free radical chain mechanism (→ Vitamins). Carotenoids and a number of natural and synthetic phenolic compounds, e.g., butylated hydroxyanisole (BHA) and butylated hydroxytoluene (BHT), inhibit oxidation (→ Antioxidants).

Hydrogenation of the unsaturated fatty acid components of fats can be used (1) to convert liq-

uid oils to margarine or other semisolid products and (2) to decrease the susceptibility to oxidation. The extent and selectivity of hydrogenation can be controlled by the choice of reaction conditions (e.g., temperature, pressure and catalyst). A simplistic illustration of the possible reactions during hydrogenation of linolenate is as follows:

Normally fats are only partially hydrogenated because complete saturation would yield products that are too hard and brittle.

Polymerization of unsaturated fatty components may occur during commercial frying operations. Appreciable polymerization causes an increase in the viscosity and foaming of frying fats. Research with experimental animals indicates that polymers are poorly absorbed from the intestinal tract and some have been reported to be toxic [49].

Phospholipids or phosphatides are present in all fats and fat-containing foods; however, these compounds are removed during the refining of fats. Phospholipids consist of polyhydric alcohols (usually glycerol) combined with fatty acids, phosphoric acid, and a nitrogen-containing group. Phospholipids are surface active because they contain a lipophilic and hydrophilic portion. Consequently, they are emulsifying agents and are the natural emulsifiers in fluid dairy products. The fatty acid groups are usually more unsaturated than those found in triglycerides. The phospholipids in milk are particularly rich in polyunsaturated fatty acids and are on the surface of the fat globules. Consequently, they are more susceptible to oxidation than the unsaturated triglycerides.

Dietary Aspects. Fats play a significant dietary role by providing calories and essential fatty acids, by serving as vitamin carriers, and by increasing the palatability of food. However, excessive consumption can adversely affect health. High intake of cholesterol and saturated fatty acids may increase the risk of cardiovascular diseases in some susceptible individuals; in many others, no relationship has been found between diet and blood cholesterol. By contrast, increasing the relative amount of polyunsaturated fatty acids can be desirable. The changes can be achieved by eating less animal, coconut, or palm fats and more polyunsaturated vegetable or marine oils. However, some of this latter group, such as older varieties of rapeseed and herring oils may contain a high concentration of erucic acids [6]. Feeding rats diets with high erucic acid content caused an infiltration of fat into heart tissues. The oil from seeds of some rape varieties are low in erucic acid and processing treatments are being developed to remove it from marine oils.

3.4. Carbohydrates (→ Carbohydrates), [6], [23], [24], [35]

Composition. Carbohydrates are compounds containing carbon, hydrogen, and oxygen and may be classified as follows:

1) Monosaccharides: pentoses and hexoses
2) Oligosaccharides: di-, tri-, and tetrasaccharides
3) Polysaccharides (glycans) (→ Starch and Other Polysaccharides):
   Homoglycans: pentosans, hexosans (cellulose, dextrin, glycogen, and starch)
   Heteroglycans: gums, pectins, hemicellulose

The main carbohydrates in animal organisms are glucose and glycogen and in milk primarily the disaccharide lactose. Plants contain a wide range of all three classes of saccharides, with cellulose being the main structural carbohydrate and starch the main storage carbohydrate.

Properties. Monosaccharides are polyhydroxy compounds with either an aldehyde or ketone group and are the building blocks for oligo- and polysaccharides. The mono- and disaccharides (i.e., the sugars) are primarily responsible for the sweetness of foods. Sugars differ considerably in sweetness, with fructose and sucrose being the sweetest mono- and disaccharides, respectively [46]. The saccharides also vary with respect to solubility. Lactose (i.e., milk sugar) is much less soluble than sucrose and crystallizes during storage of products such as sweetened condensed milk or ice cream. However, the rate of crystallization and size of crystals can

be controlled by proper manufacturing and handling practices. During storage of products such as peas and sweet corn, the sugar is converted enzymatically to starch, which decreases sweetness and increases firmness. Storing potatoes at low temperature favors conversion of starch to sugar. Potatoes that are fried after low-temperature storage develop more brown color, resulting from the Maillard browning reaction between the sugars and the potato proteins (see Section 3.2).

Reactions. When sugars are heated in the absence of water or in concentrated solution, a complex series of reactions occurs that leads to *caramel formation.* Caramel pigment formation can be considered a nonenzymatic browning process in the absence of nitrogen. This process involves anomeric shift, ring size alteration, cleavage of some glycosidic linkages and creation of others, condensation, isomerization, dehydration, fragmentation, and browning [23], [46]. During the course of these reactions, a variety of compounds are produced, including 1,2-anhydro-α-D-glucose; 1,6-anhydro-β-D-glucose; 1,3′; 2,2′-dianhydro-β-D-glucopyranosyl-β-D-fructofuranose; caramelan ($C_{24}H_{36}O_{18}$), a bitter tasting pigment; caramelen ($C_{35}H_{50}O_{25}$); and volatile compounds such as diacetyl (2,3-butanedione), acetic acid, and formic acid. A typical caramel flavor has been attributed to 4-hydroxy-2,3,5-hexanetrione and 4-hydroxy-2,5-dimethyl-3(2*H*)-furanone [47].

The trisaccharide raffinose and the tetrasaccharide stachyose are found in legumes. These oligosaccharides are not readily absorbed, but they undergo *fermentation* in the large intestines [46]. This leads to gas production and flatulence, which tends to limit the consumption of legumes.

Starch. Starch, a polymer of D-glucose, is a major source of energy in the human diet (→ Starch and Other Polysaccharides). Starch can be classified into the following three types:

1) amylose: essentially a linear polymer of α-(1 → 4)-linked pyranose rings
2) amylopectin: mostly α-(1 → 4) linkages and 4 – 5 % α-(1 → 6) linkages to yield a branched structure
3) modified starch: a processed form of corn, wheat, or tapioca starch

Amylose represents ca. 17 – 30 % of the total starch in the commonly occurring natural starches. However, in some varieties of pea and corn starch, the amylose content may be as high as 75 %. By contrast, waxy corn starch contains only amylopectin. Some properties of various corn starches are shown in Table 8.

Starch occurs in plants in the form of discrete granules that have species-specific shapes and sizes. For example, potato starch granules are egg-shaped and large (15 – 100 µm), whereas rice starch granules are round and small (3 – 9 µm). Granules are insoluble in water and, when heated, they start to swell at the so-called *gelatinization temperature,* i.e., the temperature at which some of the intermolecular hydrogen bonds are broken. Generally starches with large granules have lower gelatinization temperatures than those with small granules. This temperature is also affected by pH, heating rate, and the presence of salts and sugars. Swelling is inhibited by C-16 or C-18 fatty acids or by monoglycerides that form inclusion complexes with helical amylose. Heating aqueous starch suspensions above the gelatinization temperature causes them to become viscous and translucent. When a cooked starch is cooled gradually, the linear portion may form a precipitate of spherical crystals. This phenomenon is called retrogradation and depends on the size, shape, and concentration of the starch molecules and on the temperature. Freezing greatly accelerates retrogradation [6, p. 157].

Starch can be modified by *chemical treatments* to enhance specific properties (some examples are shown in Table 8). Starch can be hydrolyzed to give a variety of products, depending on the composition of the raw starch and the method of hydrolysis, i.e., acid, enzymatic, or combined acid–enzymatic treatment. The extent of hydrolysis is often expressed in terms of its dextrose equivalent (DE) (→ Enzymes, Chap. 4.2.5.; → Glucose and Glucose-Containing Syrups). Low DE hydrolyzates are used to increase viscosity and to serve as flavor carriers; high DE hydrolyzates impart sweetness. The sweetness can be increased by treatment with D-glucose isomerase, which converts D-glucose to D-fructose.

Table 8. Properties of various corn starches [24]

Type	Amylose: amylopectin	Gelatinization temperature, °C	Distinguishing properties
Normal	1 : 3	62 – 72	poor freeze– thaw stability
Waxy	0 : 1	63 – 72	minimal retrogradation
High amylose	3 : 2 – 4 : 1	66 – 92	granules less birefringent than normal starches
Acid-modified	variable	69 – 79	decreased hot-paste viscosity compared with unmodified
Hydroxyethylated	variable	58 – 68 (DS 0.04)	increased paste clarity, reduced retrogradation
Phosphate, monoesters	variable	56 – 66	reduced gelatinization temperature, reduced retrogradation
Cross-linked	variable	higher than unmodified depends on degree of cross-linking	reduced peak viscosity, increased paste stability
Acetylated	variable	55 – 65	good paste clarity and stability

Table 9. Selected properties of some polysaccharide gums [24]

Name	Principal monosaccharide constituents	Source	Distinguishing properties
Guar	D-mannose, D-galactose	*Cyamopsis tetragonolobus*	high solution viscosity at low concentration
Locust bean gum	D-mannose, D-galactose	*Ceratonia siliqua*	synergistic with carrageenan
Gum arabic	D-galactose, D-glucuronic acid	*Acacia*	high water solubility
Gum tragacanth	D-galacturonic acid, and D-galactose, L-fucose, D-xylose, L-arabinose	*Astragalus*	stable over wide pH range
Agar	D-galactose, 3,6-anhydro-L-galactose	Red seaweed	forms extremely strong gels
Carrageenan	sulfated D-galactose, sulfated 3,6-anhydro-D-galactose	Irish moss (*Chondrus crispus*)	forms chemically set gels with K^+
Alginate	D-mannuronic acid, L-guluronic acid	Brown seaweed (*Macrocystis pyrifera*)	forms chemically set gels with Ca^{2+}
Dextran	D-glucose	*Leuconostoc mesenteroides*	crystallization inhibitor in candies and frozen desserts
Xanthan	D-glucose, D-mannose, D-glucuronic acid	*Xanthomonas campestris*	dispersions are highly pseudoplastic

Polysaccharides. Pectic substances and gums are two groups of plant polysaccharides that can be used to modify food texture (→ Polysaccharides). Pectic substances are polymers of $1 \rightarrow 4$-linked galacturonic acids, which are found in the middle lamella of plant cells. Part of the carboxyl groups of polygalacturonic acids are esterified, and part neutralized by one or more bases. Pectins with at least 50 % of the carboxyl groups methylated form gels in the presence of sugars. Pectins with a low methoxyl content can form gels, in the absence of sugar, because of cross-linking between carboxyl groups and divalent cations, especially calcium. The composition and properties of a number of gums are shown in Table 9.

Cellulose. Cellulose, the most abundant natural carbohydrate, is a high molecular mass polymer of anhydro-β-D-glucopyranose units linked by $(1 \rightarrow 4)$ glycosidic bonds (→ Cellulose). Because the human digestive tract lacks enzymes that can hydrolyze cellulose, it is indigestible, although it does provide fiber. Cellulose reacts with ethers to form products called methylcellulose, hydroxypropylcellulose (HPC), carboxymethyl cellulose (CMC), and microcrystalline cellulose (CM). These modified celluloses are used as stabilizers in a variety of products (→ Cellulose Ethers).

Hemicelluloses and *pentosans* are noncellulosic, nonstarchy complex polysaccharides that occur in plant tissues along with cellulose. Hemicelluloses are insoluble in water, whereas pentosans are soluble in water. These polysaccharides usually contain two to four different sugars. They frequently exist in single chains of β-$(1 \rightarrow 4)$-linked D-xylopyranose units and may have L-arabinofuranose units attached at C-3 or possibly at C-2. Because these compounds are not digestible, they contribute to the dietary fiber content of food. The hemicelluloses may improve the water-binding capacity of flour, the mixing quality of bread dough, and the loaf volume of bread.

Dietary Aspects. Carbohydrates provide an efficient and inexpensive energy supply. Many United States nutritionists recommend that United States consumers increase their carbohydrate consumption so that it supplies at least 58 % of the total energy intake (carbohydrates already supply more than this amount of energy in the diets of consumers in countries with

lower meat consumption). Furthermore, it has been recommended that the dietary intake of refined and processed sugar be reduced so that the energy intake from this source does not exceed 10 %. Although this recommendation has not received unanimous support, it is based on evidence that simple sugars may contribute to dental caries and that the more complex carbohydrates have more potential advantages. Consumers are also recommended to include enough fiber in their diet to minimize constipation and diverticular diseases. In addition, fiber is believed to (1) reduce the risk of cardiovascular disease by lowering serum cholesterol and (2) reduce cancer of the colon and rectum by binding carcinogens and speeding their excretion.

3.5. Mineral Components

Occurrence. Mineral or inorganic components occur in foods as salts or in combination with organic compounds [6], [48], [49]. Such components are commonly divided into two groups: the major minerals and trace elements. The *major minerals,* which are essential nutrients, include potassium, sodium, calcium, magnesium chloride, sulfate, and phosphate. The *trace elements* have been divided into three groups:

1) essential nutritive minerals, which include fluorine, silicon, vanadium, chromium, manganese, iron, cobalt, nickel, copper, zinc, selenium, molybdenum, tin, and iodine
2) nonnutritive, nontoxic elements, including aluminum and boron
3) nonnutritive, toxic elements, including mercury, lead, arsenic, cadmium, and antimony

Some of the minerals exist in food as soluble salts, especially the monovalent species. These minerals contribute to the taste and the osmotic pressure of the aqueous phase. Some of the polyvalent ions are present as an equilibrium mixture of ionic, soluble nonionic, and colloidal species. Such equilibria exist in milk and meat. Many minerals are present as chelates, including the iron-containing hemoglobin and myoglobin, the magnesium-containing chlorophyll, the cobalt-containing vitamin B_{12}, and the copper-containing polyphenoloxidase.

Calcium, an important nutrient, forms complexes with a variety of compounds, including oxalates, phosphates, citrates, alginates, pectates, and caseinates. Oxalates bind the calcium so that it is unavailable as a nutrient. Calcium citrates and phosphates affect the colloidal stability of proteins in products such as evaporated milk. Calcium alginates and pectates are involved in producing stable viscous products. USDA reports indicate that many American diets contain less than the recommended amount of calcium. Calcium affects bone structure and therefore calcium deficiency could contribute to osteoporosis, a disorder in which bones become less dense and more fragile. This disorder is particularly prevalent in older women (postmenopause). Although several factors affect osteoporosis, many scientists believe that extra calcium may help prevent osteoporosis. This information has led to the fortification of a variety of foods with calcium. Some experts question the wisdom of such a massive fortification effort.

Reactions. Canned foods may react with tin, iron, or lead in the can and produce color changes resulting from reactions between the metals and polyphenols in the food. Calcium and magnesium may be absorbed by peas if they are cooked in hard water. When dry beans are soaked in water, some minerals may leach into the water.

3.6. Vitamins

Vitamins are organic compounds that are required in small amounts in the diet for growth and maintenance of life (→ Vitamins) [7], [35], [48–50]. Originally vitamins were all believed to be amines, and hence the name "vitamines" was chosen. When some of them were found not to be amines, the "e" was dropped from the word.

Vitamins have been divided into two groups, namely, fat-soluble vitamins (A, D, E, and K) and water-soluble vitamins (C and the B complex). *Fat-soluble vitamins* are stored in the liver and can be retained for long periods of time. This can lead to vitamin toxicity if the accumulated level gets too high. *Water-soluble vitamins* are only retained for short periods of time, and thus, the supply can be depleted rapidly.

Scientists worldwide have studied vitamin requirements and published dietary guidelines. Ta-

Table 10. Recommended daily dietary allowances [a] [51]

	Age	Weight		Height		Protein	Fat-soluble vitamins			Water-soluble vitamins							Minerals

[a] Revised 1980. The allowances are designed for the maintenance of good nutrition of practically all healthy people in the United States. They are intended to provide for individual variations among most normal persons under usual environmental stresses. Diet should be based on a variety of common foods to provide other nutrients for which human requirements have been less well defined.

[b] Retinol equivalents. 1 retinol equivalent = 1 µg of retinol or 6 µg of β-carotene.

[c] As cholecalciferol. 10 µg of cholecalciferol = 400 I.U. vitamin D.

[d] Tocopherol equivalents. 1 mg of *d*-α-tocopherol = 1 α T.E.

[e] 1 N.E. (niacin equivalent) is equal to 1 mg of niacin or 60 mg of dietary tryptophan.

[f] The folacin allowances refer to dietary sources as determined by *Lactobacillus casei* assay after treatment with enzymes (conjugases) to make polyglutamyl forms of the vitamin available to the test organism.

[g] The RDA for vitamin B_{12} in infants is based on average concentration of the vitamin in human milk. The allowances after weaning are based on energy intake (as recommended by the American Academy of Pediatrics) and consideration of other factors such as intestinal absorption.

[h] The increased requirement during pregnancy cannot be met by the iron content of habitual American diets nor by the existing iron stores of many women; therefore, the use of 30–60 mg of suplemental iron is recommended. Iron needs during lactation are not substantially different from those of nonpregnant women, but continued supplementation of the mother for 2–3 months after parturition is advisable to replenish stores depleted by pregnancy.

Table 11. Approximate percentage contribution of fruit–vegetable food group to total nutrient supplies [52]

Energy and nutrients	Fruit and vegetable contribution, %					
	Citrus fruits	Other fruits	Potatoes and sweet potatoes	Dark-green and deep-yellow vegetables	Other vegetables including tomatoes	Total, %
Energy	0.9	2.2	2.7	0.3	2.5	9
Calcium	0.9	1.2	0.9	1.6	4.9	10
Phosphorus	0.7	1.1	3.9	0.7	5.0	11
Iron	0.8	3.3	4.4	1.6	9.0	19
Magnesium	2.2	3.9	7.1	2.1	10.4	26
Vitamin A	1.5	5.5	5.3	21.2	15.5	49
Thiamin	2.8	1.8	6.2	0.9	6.9	18
Riboflavin	0.5	1.5	1.7	1.1	4.5	9
Niacin	0.9	1.7	7.1	0.7	6.1	16
Vitamin B_6	1.2	5.5	11.2	1.7	9.2	28
Ascorbic acid	26.3	11.4	18.0	8.3	27.6	92

Table 12. Stability of nutrients∗ [50]

	pH			Air or oxygen	Light	Heat	Max. cooking loss, %
	pH < 7 (acid)	pH 7 (neutral)	pH > 7 (alkaline)				
Vitamins							
Vitamin A	U	S	S	U	U	U	40
4-Aminobenzoic acid	S	S	S	U	S	S	50
Ascorbic Acid (C)	S	U	U	U	U	U	100

Tryptophan	U	S	S	S	U	S	15
Valine	S	S	S	S	S	S	10
Essential fatty acids	S	S	U	U	U	S	10
Mineral salts	S	S	S	S	S	S	3

∗ S = stable (no significant destruction); U = unstable (significant destruction)

ble 10 shows the Recommended Daily Dietary Allowances, which was published by the United States National Academy of Science [51].

Most natural foods contain several vitamins, but the number and concentration vary, as illustrated in Table 11. Just like other constituents, the concentration of vitamins in a particular food depends on factors such as genetics, climate, weather, soil fertility for plants or feed for animals, maturity at the time of harvest or slaughter, postharvest handling and storage, and processing or cooking procedures. The effects of pH, oxygen, light, and heat on vitamin stability are shown in Table 12.

Table 13. Types of enzyme-catalyzed food modifications∗

Type of modification	Enzyme	Consequence
Flavor	ribonucleases	producing nucleotide flavor enhancers
	lipase	producing strong flavored, volatile free fatty acids
	protease	producing bitter flavor in cheese
	sulfhydryl oxidase	reducing cooked flavor in milk
	naringinase	debitterizing grapefruit juice
	thioglycosidase	regenerating flavors in dehydrated cabbage
Color	polyphenoloxidase	enzymatic browning of fruits, tea, and coffee
	lipoxygenase	oxidizing carotenoid pigments (e.g., bleaching of flour)
	glucose oxidase	removing sugar from eggs and reducing their browning
	pectinases	clarifying fruit juices
Texture	bromelain, papain	tenderizing meats
	cellulases	tenderizing vegetables
	amylases	reducing viscosity of starch gels
	rennet	coagulating milk
	polygalacturonase	softening of fruits
Nutritive value	cellulases	removing inedibles
	tannase	removing inhibition of protein digestion by tannins
	lactase	compensating for lactase deficiencies of some people
	thiaminase	destroying thiamin

∗ Taken from information in [7], [27], [28].

3.7. Enzymes

Enzymes are proteins with highly specific catalytic properties (→ Enzymes), [6], [7], [27], [28], [43]. Enzymes are found in all living organisms and catalyze many of the reactions that occur in natural products. Foods may contain endogenous enzymes, enzymes from microbial sources, as well as enzymes that are added for specific purposes. Enzymes may affect flavor, color, texture, and nutritive value of foods (see Table 13).

The velocity of enzyme-catalyzed reactions depends on temperature, pH, ionic strength, and the concentrations of enzyme, substrate, activators, and inhibitors. A plot of velocity versus temperature, pH, or ionic strength usually produces a bell-shaped curve. The peak of the curve represents the optimal conditions. The optimal conditions for some enzymes are restricted to a narrow range, whereas others exhibit a broad range. Because enzymes are proteins, they can be altered by denaturating agents or treatments. Thermal processing and freezing can markedly reduce enzymatic activity.

Enzymes vary with respect to their heat sensitivity, but they each have a specific inactivation temperature. Therefore, processing temperatures that inactivate undesirable enzymes can be chosen. Vegetables may be scalded or blanched to inactivate enzymes prior to freezing. The temperature needed to inactivate enzymes in foods may be higher than that required in simple model systems. For example, the fat and other solids in milk protect the lipase so that the heat treatment required to inactivate lipase increases as the solids content increases [53]. Some enzymes may become reactivated during storage (e.g., phosphatase in cream and catalase in spinach).

The rate of an enzymatic reaction can be influenced by factors affecting the contact between enzyme and substrate. Rupture of cell walls or other protective membranes by mechanical means or by freezing can increase the reaction rate. Homogenization of fat-containing fluid dairy products increases lipolysis by disrupting the fat globule membrane and increasing the surface area of the substrate.

3.8. Miscellaneous Components

3.8.1. Flavor Components

The flavor components of foods consist of substances that elicit taste and odor responses (→ Flavors and Fragrances; → Foods, 3. Food Additives, Chap. 4.7.;→ Foods, 3. Food Additives, Chap. 4.8.;→ Foods, 3. Food Additives, Chap. 4.10.;→ Foods, 3. Food Additives, Chap. 4.11.) [6], [7], [25], [53–58]. Salt, acid, sweet, and bitter are the main taste substances. There are many more odor components, including those derived from the degradation of the major constituents (i.e., lipids, carbohydrates, and proteins) plus a variety of other volatile aliphatic, aromatic, and heterocyclic compounds. Thousands of odor or aroma compounds have been identified, but attempts to classify them have not been completely successful.

Lipids degrade to give potent flavor compounds, including volatile fatty acids, lactones, methyl ketones, and a variety of carbonyl compounds arising from oxidation. Protein hydrolysis yields bitter-tasting amino acids and peptides. Microbial degradation of proteins pro-

duces amines and other offensive-smelling compounds. Hydrolysis of polysaccharides can yield sweet-tasting monosaccharides and polysaccharides. Carbohydrate fermentation yields a variety of alcohols and esters. Heat-induced interactions between carbohydrates and proteins yield numerous flavorful Maillard browning reaction products, including nitrogen heterocyclics (pyrroles, pyrazoles, pyridines, pyrazines, and oxazolines) and oxygen heterocyclics (furans, pyrones, furfuryl alcohols, furanones, and maltols).

Sulfur-containing compounds, such as disulfides, trisulfides, isothiocyanates, and thiazoles, have potent odors and are found in vegetables such as cabbages, cauliflower, onions, and garlic. Sulfur compounds may also originate from light- or heat-induced degradation of sulfur-containing amino acids [53], [55].

Esters contribute to the flavor of many fruits, but each fruit has its unique blend of esters and other components. In some cases, specific components that contribute to the unique flavor are called character impact compounds. Isoamyl acetate, ethyl 2-methylbutyrate, methyl anthranilate, and γ-decalactone have been identified as impact compounds in bananas, apples, grapes, and peaches, respectively [55].

Astringency, the puckery sensation that is perceived in the mouth, results from stimulation of the trigeminal nerve system rather than the chemoreceptor system that responds to taste. Tannins or other polyphenols are responsible for the astringency of products like tea, wine, and cranberry juice. *Pungency,* the stinging sensation that is perceived in the nose, also involves trigeminal nerve stimulation. Many spices contain pungent components including capsaicin from chili peppers and gingerol from ginger.

3.8.2. Natural Pigments [6], [7], [35]

The appearance and color of food are important attributes because the consumer's first judgement of its quality is based on its appeal to the eyes. The color indicates the maturity of fruits and vegetables, the freshness of meats and salads, and the extent of nonenzymatic browning in the case of heated products.

The chlorophylls, hemoglobins, and myoglobins are *tetrapyrrole pigments,* which have a basis skeleton of four pyrrole rings connected by methine bridges with a metal in the center of the complexes. The chlorophylls are magnesium chelates, and the other two pigments are iron chelates. The chlorophylls are esterified with phytol (a C_{20} alcohol), which accounts for their solubility in organic solvents and insolubility in water. Myoglobin is an iron-containing porphyrin linked to a 153-residue polypeptide. Hemoglobin contains four polypeptide chains and four porphyrin or heme groups. The presence of iron in these pigments accounts for their sensitivity to oxygen.

Isoprene groups provide the basic structure for the *carotenoid pigments.* These pigments include the carotenes, which are hydrocarbons, and the xanthophylls, which are oxygenated derivatives of the carotenes. They are soluble in fat and are responsible for many of the yellow and red colors of plant and animal products and the red color of shells, exoskeletons, and skins of crustaceans, mollusks, and fishes. The carotenoids are unsaturated and, therefore, are susceptible to oxidation when exposed to oxygen and light. They become oxidized quite rapidly in the presence of unsaturated lipids and lipoxygenase.

A number of water-soluble *phenolic constituents* of plants contribute to the color of their leaves, flowers, and fruits. The red anthocyanins and yellow flavonoids are the principal phenolic chromophores. Both of these types are glycosidic derivatives of phenylbenzopyrylium (flavylium) salts, but they differ with respect to the substitution on the flavylium nucleus. Tannins, which range in appearance from colorless to yellow or brown, represent another group of phenolic compounds. The two types of tannins are condensed tannins, which are polymers of catechin or related compounds, and hydrolyzable tannins, which are polymers of gallic acid esters.

Betalains are a group of *nitrogen-containing compounds* with colors resembling those of the anthocyanins and flavonoid pigments. Betanin is a red betalain that is found in beets and has potential as a replacement for synthetic red colors.

A summary of some characteristics of pigments is listed in Table 14.

Table 14. Characteristics of natural pigments

Pigments	Color in		Sensitivity to [a]	
	Acid	Base	Oxygen	Heat
Anthocyanins [b, d]	red	blue	+	++
Flavonoids [b]	white	yellow	+	+
Carotenoids [c]	orange	orange	++	Ins.
Chlorophylls [c]	olive green	bright green	Ins.	+
Myoglobins [b]	red	darkens	+	+
Betalains [b] (from beets)	red	red [e]	+	+

+ = moderately sensitive; ++ = highly sensitive.
[a] Ins. = Insensitive;
[b] Water soluble.
[c] Water insoluble.
[d] React with Fe, Al, or Sn to give blue or green colors.
[e] Betanin, the major pigment of beets, is red over the pH range of 3.5 – 7.0; above pH 7 the color shifts toward blue, which becomes obvious above pH 9.

3.8.3. Undesirable or Potentially Undesirable Constituents

Food may contain constituents that are toxic or that reduce the availability of nutrients or impart unacceptable sensory characteristics [5–7], [49], [59]. Some of these undesirable constituents may be naturally present in food, may be produced by microbes, or may be unintentionally introduced or produced during processing, handling, or storage of food. Even some intentional additives, such as saccharin, may be considered undesirable by some individuals.

Some naturally occurring undesirable components are listed in Table 15. Fungi can produce potent toxins including ergot, which has been found on wheat, and aflatoxin on peanuts. Botulinum toxin is the most potent bacterial toxin, but the enterotoxins from *Staphylococcus aureus* are more common. Unintentional additives that are potentially dangerous include fumigants, such as ethylene oxide and methyl bromide; solvents, such as trichloroethylene, which reacts with cysteine to form toxic components; polycyclic aromatic hydrocarbons from wood smoke; and numerous pesticides, herbicides, and antibiotics that are used in the production of foods.

Table 15. Poisons and antinutritional properties of foods [5]

Poison and antinutritional factor	Disease, ailment, or disease potential	Food
Allyl isothiocyanate	skin irritant	horseradish, mustard
Amines, biological	can elevate blood pressure with certain tranquilizers; can cause death	natural cheese, Chianti (wine), yeast extracts, bananas, pineapples, tomatoes, pumpkins, squash, cucumbers
Carcinogens		
Safrole	found to cause cancer in mice	cinnamon, nutmeg, sassafras
Tannic acid	known to cause liver tumors in rats	tea, nuts, fruits
Benzopyrene	known carcinogen	cabbage, charcoal-grilled meat, spinach, lettuce, tea
Lemon and sesame oils	cocarcinogenic properties	lemon and sesame oils
Enzyme inhibitors of		
Trypsin	growth retardation in animals	soybeans, kidney beans, lima beans
Chymotrypsin	growth retardation	Irish potatoes, egg whites
Cholinesterase	block transmission of nerve impulses	radishes, carrots, celery, potatoes, broccoli, eggplant, sugar beet, asparagus, Stayman apple, Valencia orange
Solanine	cholinesterase inhibition, teratogen, abortion, and fetal resorption agent	potatoes (blighted or stressed)
Factor produced by Faba beans	hemolytic anemia in persons predisposed to toxic factor	Faba bean (*Vicia faba*)
Glycosides		
Cyanogens	cyanide poisoning	Lima beans, cassava, almonds, black-eyed peas, wild black cherries, kidney beans, peach pits, apricot pits, choke cherry pits

4. Food Law

Food regulations and laws emerged as soon as consumers began to depend on others for some of their food [1], [2], [49], [60–70].

Table 15. (Continued))

Goitrogens	goiter	soybeans, rapeseed, white turnips, cauliflower, peaches, pears, strawberries, Brussels sprouts, spinach, carrots, rutabaga, cabbage
Glycosides of some honey	potent heart stimulant	honey from bees obtaining sugars from mountain laurel, rhododendron, azalea, oleander
Gossypol (or sterculic acid)	poisoning of farm animals, reproduction problems in rats and chickens, cocarcinogen in trout	pigment gland of cottonseed
Hemagglutinins	growth inhibition	soybeans and other legumes
Metal binding factors		
Phytates	interfere with calcium absorption	cereals
Oxalates	interfere with calcium absorption	spinach, cashews, almonds, cocoa, rhubarb, Swiss chard, beet tops, parsley, celery, currants, prunes, beans, soybeans
Mushroom poisons	food poisoning	inedible mushroom varieties
Myristicin	hallucinogen	nutmeg, carrots, celery
Nitrates (and nitrites)	cocarcinogen methemoglobinemia	spinach, smoked foods, green leafy vegetables
Shellfish poisoning	lethal toxin of shellfish consuming certain algae	shellfish
Stimulants (caffeine, theobromine, theophylline)	hypertension	coffee, tea, cocoa
Vitamin A	found to cause disturbances in rat offspring	cheese, butter, yellow vegetables, fruits
Vitamin D	vascular lesions, mental retardation; vitamin D and nicotine-arterial thrombosis in susceptible rabbits	butter, egg yolks, fish oil, liver, salmon, tuna

History. In 1700 BC the Babylonians created laws prohibiting adulteration of wines. Mosaic and Egyptian laws outlined procedures for selecting and slaughtering cattle and the subsequent handling of meat. The Egyptians also described the proper procedure for making bread. Several centuries before Christ, India had regulations prohibiting adulteration of grain and edible fats and oils. Roman laws required products to be unspoiled. They also created an inspection service to oversee commercial meat and bread operations. The Romans in Constantinople established stringent measures to prevent adulteration of spices. In 1120 the death penalty was threatened in Germany for those who adulterated wine. In 1319 a butcher was put in pillory for selling putrid beef. HENRY VIII forbade the use of hops in beer. In Germany in 1532 under CHARLES V, penalties were established for adulterating spices and other merchandise.

Public opinion about food quality was aroused in England in 1820 by FREDERICK ACCUM's treatise on food adulteration [71]. According to him, it was not uncommon to find sulfuric acid in vinegar; gravel, leaves, and twigs in black pepper; roasted grains, carrots, or scorched beans and peas in coffee; water in milk; alum, burned sugar, lime, and lead salts in wine; and sand, dust, lime, and pulp in sugar [72]. Similar adulterations also occurred in other countries, which stimulated the proliferation of regulations.

The rate and sequence of development of food laws varied from country to country. However, in all countries the main objective was to ensure a pure, safe food supply. Most of the early laws were designed to prevent adulteration of foods and misrepresentation of quality. This led to the development of standard weights and measures, as well as qualitative methods to detect impurities. At first, purity was determined by visual inspection, sieving, or filtering to separate foreign objects and by tasting to detect flavor abnormalities [72]. The demand for more regulations grew as consumers became more dependent on foods from distant places and on processed or formulated foods. Laws that defined product contents were developed. At first these definitions were expressed in terms of ingredients used or methods of preparation. Regulatory definitions became more specific and detailed as science progressed. Standards of identity were established for foods, including cereal and dairy products, salad dressings, vegetables oils, margarines, butter, and canned fruits and vegetables. Many of these standards stipulated the composition of the products so that failure to meet these specifications constituted a violation of the law. These standards put pressure on the food producers and processors to maintain quality.

During this century there has been a tremendous increase in concern about the wholesomeness and safety of food and a concomitant in-

crease in rules and regulations [70]. Regulations cover every aspect of production, processing, and handling of foods. At the production level, regulations govern the use of pesticides, herbicides, antibiotics, and in some cases, hormones. With perishable products like milk, regulations govern the type of milking facilities and equipment, as well as storage conditions. At the processing level, regulations are even stricter and include rules pertaining to type and design of processing equipment, processing and sanitizing procedures, packages, packaging procedures, and storage conditions.

Research showing the relationship between nutrient intake and health increased public concern about the nutritional quality of foods. These concerns led to the development of dietary guidelines in the United States and to rules governing the use of nutritional claims on food labels and in food advertisements. Regulations establishing maximum fat contents for products such as hamburgers arose from concern over excessive fat consumption. On the other hand, laws were introduced requiring fortification of low-fat milk with vitamin A because of concern over the impact that lowering fat intake might have on vitamin A intake. This simply illustrates the risks and benefits associated with dietary modification. Many regulatory issues address similar but more complex problems and are the subject of numerous publications [49], [59], [69], [70].

The "Delaney Clause" is one of the most controversial pieces of U.S. food regulations. It is part of the 1958 food additive amendment, which forbids the addition to food of any material shown to produce cancer in animals in any dose. This restriction has helped to prevent the approval of potentially harmful additives, but in some cases it may have prevented the use of beneficial additives. As analytical methods have become more sensitive, previously undetected substances are now being detected. In some cases the analytical threshold may be lower than the toxicity threshold.

The agencies responsible for making and enforcing laws vary from country to country. In the United States, some foods are also regulated by state, county, and municipal governments. Even within the same government, regulatory functions are divided. For example, in the United States the Food and Drug Administration regulates most foods and beverages, but the U.S. Department of Agriculture (USDA) regulates meat and poultry products, and the Bureau of Alcohol, Tobacco, and Firearms (BATF) regulates alcoholic beverages [62]. The Federal Trade Commission (FTC) regulates advertising. Each country has its own regulatory organization so that a food company wishing to export its product must determine local regulations. Many trade organizations and governments try to standardize regulations to facilitate trading, although occasionally they deliberately create barriers.

The International Dairy Federation (IDF) has contributed much to the standardization of dairy products and regulations. Regional alliances, such as the European Economic Community [68], and worldwide organizations, such as the International Standard Organization (ISO) [67], Food and Agriculture Organization (FAO), and World Health Organization (WHO) are working on standardization of all food products and laws [61]. The FAO/WHO Codex Alimentarius Commission has probably contributed the most toward standardization.

5. Documentation

Besides numerous scientific and trade journals, a variety of other sources contain information pertaining to foods. Textbooks [6], [7], [29], [35], [49], and encyclopedias [73–75] have extensive bibliographies. However, the most complete listing of food organizations and resources, including computer data banks, are contained in reference guides [76–79].

6. Feeds

History. The scientific feeding of livestock and poultry started as a means of disposing of refuse and byproducts of grains and other human foods. For over 200 years, water-powered grist mills were used to grind and process wheat and other grains destined for human consumption [80]. As society became more industrialized, oilseed processing, milk processing, and meat rendering yielded undesirable byproducts, the disposal of which was routinely accomplished through dumping in local lakes and rivers.

As livestock and poultry producers gradually learned about the physiological functions of

their animals, they became interested in using the inexpensive byproducts. As these products began to gain economic value to the producers, the commercial feed industries arose. To evaluate the *feeding value* of feedstuffs, two basic scientific approaches needed to be developed:

1) A definition of the nutritional requirements for various production methods needed to be established.
2) Reliable, predictable chemical analyses of feedstuffs needed to be correlated to the nutritional requirements of the animals.

Most of the early feeding studies were conducted in Germany [81]. The first set of scientific *feeding standards* is generally attributed to the German scientist Thaer, who in 1810 used meadow hay as a standard to which extractable nutrients from other feeds were compared and assigned "hay values." In 1827, Prout established protein, fat, and carbohydrates as essential organic nutrients. An extension of these principles can be found in Grouven's work (1859), which used this system of protein, fat, and carbohydrates to develop a sophisticated feeding standard system for farm animals [82]. Another German scientist, Wolff, in 1864, developed a feeding standard system based on actual farm trials in which digestibility of nutrients was measured. In 1897, Lehmann published the *Mentzel Lengerke Calendar,* which adapted Wolff's system so that standards were stated on a dry-matter basis, giving rise to what was to become known as the Wolff–Lehmann feeding standards [81].

Throughout the latter part of the 19th century and the first 50 years of the 20th century, other feeding standard systems arose throughout the world (available fuel values, Atwater, 1890; starch values, Kellner, 1907; Scandinavian Feed Unit, Woll, 1912; dairy standards by Haecker, 1914; digestible true protein and net energy, Armsby, 1915). In the United States, Henry first published a landmark book entitled *Feeds and Feeding* in 1898 [83]. The standards developed by Henry, as well as those carried on and refined by his later collaborator Morrison, were the most widely used in North America for the first half of the 20th century [81].

Currently, a wide range of feeding standards can be found throughout the world, largely reflecting the feeding systems of the country or region. In the United States and Latin America, the recommendations of the National Research Council (NRC) of the National Academy of Sciences provide the basis for nutritional research and livestock feeding. In the British Commonwealth countries, recommendations of the Technical Committee of the Agricultural Research Council (ARC) are used. Because of rapidly expanding information on livestock and poultry nutrition, nutritional standards are under continual review and modification, the results of which are then provided in revisions of the NRC and ARC standards.

6.1. Feed Definitions

In general, *feed* can be defined as edible material(s) that are consumed by animals and contribute energy or nutrients to the animal's diet (usually refers to animals rather than humans) [84]. *Feed ingredients*, on the other hand, are defined as component parts or constituents of any combination or mixture making up a commercial feed. In many countries, the terms *feedstuffs* or *feeding stuffs* can be used interchangeably with the term *feed ingredient.*

When ingredients are mixed in proper proportions as designed by scientific formulation, a *commercial feed* or compound feed is produced. Such feed may or may not be the sole item fed to livestock and poultry because various forms of commercial feeds may be designed to be mixed with locally provided ingredients to make a *complete feed,* i.e., one that is nutritionally adequate for maintaining life or promoting production.

Terminology describing various types of commercially available feeds is imprecise and varies not only from region to region, but also from company to company. However, Figure 1 provides a generalized concept of how feeds are categorized [85]. As is discussed in Section 6.2, various forms of livestock have anatomical and physiological differences that permit or prevent them from using different types of feedstuffs. For example, ruminants have the ability to digest and effectively use fibrous materials such as hays and forages, whereas nonruminants are restricted in their ability to use such feeds. A *complete feed–ruminant* refers to a commercially prepared product that provides all nutrients required to support the form of production for which it was designed, including roughage.

Complete feed–nonruminant refers to a commercially prepared feed that provides all nutrients required to support the form of production for which its was designed; this may or may not include roughage.

Figure 1. Feed classification

A *supplement* or *concentrate* is a commercially prepared feed that is formulated to be mixed with a primary grain or roughage to provide all the nutrients required to support the form of production for which it was designed. A *base mix* or *superconcentrate* is a low inclusion commercially prepared feed designed in such a way as to require the addition of a primary source of energy (grains), a primary source of protein (such as soybean meal), or roughage. *Premixes* are commercially prepared feeds designed to provide microingredients or specialty products to a mixture of feed ingredients to make a nutritionally complete feed.

6.2. Feed Utilization by the Animal

Feeds are formulated to address specific physiological requirements of the animal for which they are intended. Each species of livestock and poultry has its own unique metabolic requirements; this fact makes a feed designed for the laying hen different from that of the growing turkey, which is different from that of the milking cow. These basic differences can be understood by comparing the digestive tracts of various commercially raised livestock and poultry species.

From a simplistic view, mammalian livestock can be divided into two general categories: ruminants and nonruminants. Additionally, the digestive system of fowl is dramatically different from that of either the ruminant or the nonruminant.

Ruminants (cattle, sheep, and goats) have the unique ability to digest and use fibrous roughages and forages such as silage, grasses, and hays because of their compartmentalized stomach. Composed of four compartments, i.e., the rumen, reticulum, omasum, and abomasum, this stomach provides a complex digestive system that makes the ruminant an effective user of byproduct types of feeds. In effect, the rumen (the largest compartment of the system) is a huge fermentation vat harboring a wide variety of microorganisms (bacteria, yeasts, protozoa, etc.). It can effectively digest cellulose and complex carbohydrates to give simple volatile fatty acids essential for energy requirements. Additionally, a complex symbiotic relationship of the microflora allows the ruminant to form amino acids and, hence, proteins from nitrogenous compounds such as urea (Fig. 2) [86]. As is the case in most fermentation systems, microorganisms also produce a wide range of B-complex vitamins, therein reducing (and in most cases, eliminating) the need for B-vitamin supplements in the feed. Once the digested materials pass through the rumen complex, digestive processes in the small and large intestines are essentially analogous to those of nonruminants.

For *nonruminants* with simple gastrointestinal tracts, such as the pig and the dog, fiber digestion and microbial synthesis of B-vitamins is restricted. These types of animals are typically

Figure 2. Protein and ammonia metabolism in the ruminant

fed easily digested types of feedstuffs such as grains, milk products, and meat products.

Several types of nonruminants, such as the horse and the rabbit, possess an enlarged cecum, which provides a means of fermentation and subsequent production of certain nutrients and increased use of fibrous feedstuffs as compared to the simple nonruminant. However, although the large cecum allows this increased use of forages, such animals do not possess the efficiency of digestion seen in the ruminant.

The digestive system of the *fowl* is very different from that of the mammal. Because birds have no teeth, mastication is almost nonexistent. The esophagus provides a passageway for feed to the crop, where the material is soaked with digestive enzymes and stored temporarily. The feed then passes to the proventriculus, which could be compared to the simple stomach of the mammal, where more digestive enzymes and acids are secreted to enhance chemical digestion. The feed is passed to the gizzard, a tough, muscular organ where the feed is mechanically crushed and ground, providing more surface area for digestion. The feed then passes to the small intestine, to the ceca, and then to the large intestine.

Feed retention is largely a function of the complexity of the digestive system. Because the digestive tract of the fowl is relatively small in

capacity and simple in structure, feed passage is rapid, as fast as 2.5 h in the laying hen. Conversely, in the ruminant where fermentation in the rumen is critical to the digestion process, feed retention time is long (up to several days). Retention time in the ruminant is a function of the type of feed provided. A high-fiber diet can be expected to take much longer to digest than a diet containing grains and easily digested ingredients [87].

6.3. Feed Components

Feeds themselves are of little value to the animal unless they can be digested to essential nutrients, which are then subsequently absorbed and used in metabolic processes. Therefore, feeds and feed ingredients are routinely evaluated for their respective nutrient profiles. The outline in Table 16 illustrates the analytical and nutritional parameters commonly used for feeding livestock and poultry. In basic feed formulation, energy and protein parameters are the primary references (→ Amino Acids; → Proteins). After these parameters are fulfilled, attention is directed to vitamins and minerals, as well as to feed additives such as growth promoters or medications (→ Vitamins).

Several systems of expressing energy and protein requirements can be found in the feed industry. For example, in the United States energy requirements are expressed in terms of the calorie, whereas the SI unit of energy is the joule (1 J = 4.18 cal). With the development of sophisticated analytical techniques for feed and the growing data base for fine-tuning formulations, amino acid formulation is used rather than total protein. In addition, many formulators use digestible, metabolizable or net energy, or protein values rather than gross energy or total protein.

6.4. Processing

Because feed is comprised of a number of raw commodities and industrial processing byproducts, the following methods of processing are used:

Particle size reduction (→ Size Reduction): grinding and rolling (crimping, cracking, and crushing)

Heating: pelletizing, extruding, flaking, roasting, cooking, and popping

Compaction: pelletizing, blocking, cubing, and crumbling

Chemical processing: tempering, fermentation

The advantages of processing are variable because of the type of animal being fed, the source of raw materials for the feed, and the wide variety of bulk densities and handling characteristics of feed ingredients. Some of the reasons for processing feed are as follows [88]:

1) Increase feed efficiency and production efficiency, thereby improving profit. However, processing is generally energy intensive, and the economic benefits must outweigh the costs of processing.
2) Alter particle size. Some ingredients need to be reduced in size for effective use by the animal and also to produce a feed that is homogeneous in particle size to prevent individual ingredients from segregating.
3) Change moisture content. Feeds can be too wet or too dry. A feed with too much moisture can physically restrict intake because of the limitation of gut "fill". Processing allows for removal or addition of water to enhance use.
4) Change the density of the feed. Bulky feeds may provide a physical "filling" of the animal, not allowing the animal to consume enough feed to meet its needs. Blocking or pelletizing produces a compact feed form, promoting increased consumption.
5) Change palatability. Often feeds containing unpalatable ingredients can have those tastes masked or blocked through processing.
6) Increase nutrient availability and eliminate detrimental effects of feed ingredients. Often raw commodities contain antinutritional factors (such as trypsin inhibitors in soybeans and in other pulses) and toxins (aflatoxins) or have limited nutritional values resulting from the physical structure of the ingredient particle (e.g., grains). Processing (heat treatment) can assist in minimizing the presence of antinutritional factors, and physical alteration of particles can increase surface area and improve digestion and absorption.

Table 16. Nutrient partitioning of feed

Energy	Gross	digestible	metabolizable	net
Protein∗	Nonprotein nitrogen	Protein		
		Nonessential amino acids		Essential amino acids
	Purines/pyrimidines Urea Ammonia	alanine asparagine aspartic acid cysteine cystine glutamic acid glutamine glycine proline serine tyrosine		arginine histidine isoleucine leucine lysine methionine phenylalanine threonine tryptophan valine
Vitamins∗∗	Fat soluble		Water soluble	
	A D E K		B-12 biotin choline folic acid niacin pantothenic acid pyridoxine riboflavin thiamine vitamin C	
Minerals	Macro		Micro	
	Calcium Phosphorus Potassium Magnesium Sulfur		cobalt copper iron iodine manganese molybdenum selenium zinc	

∗ Ruminants can effectively synthesize protein from nonprotein nitrogen, whereas poultry and nonruminants cannot; nonruminant ration formulation uses a combination of total protein and specific amino acid inclusion (methionine and lysine are the most commonly incorporated commercial amino acids).
∗∗ Ruminants can synthesize adequate amounts of water-soluble vitamins to fulfill nutrient requirements in most cases; vitamin C is generally not added to commercial feed.

6.5. Chemical Analysis

Although a feed may be complete chemically, if its constituent nutrients cannot be digested and metabolized by the animal, that feed is of little value. For example, a nonruminant has a very limited ability to convert roughages to energy because of the nature of the digestive system, while a ruminant is routinely fed fibrous materials.

In this age of computerization and sophisticated analytical technology, the primary means of chemical analysis of feed is still *proximate analysis,* developed over 100 years ago at the Weende Experiment Station in Germany. This method analyzes moisture, crude protein, ether extract, ash, crude fiber, and nitrogen-free extract.

Moisture. The water content of feed can be measured by oven drying at 135 °C until a constant mass is reached. In cases where feeds have a high content of volatile compounds, freeze drying, vacuum drying, and distillation with toluene are used.

Crude Protein. Because protein contains an average of 16 % nitrogen, crude protein values

are derived by determining the amount of nitrogen in feed by the Kjeldahl method of nitrogen analysis and multiplying this figure by 6.25. A "crude" approximation is obtained because not all proteins contain 16 % nitrogen and because not all the nitrogen in feed is associated with protein. However, this determination has been effectively used despite its inherent imprecision.

Ether Extract. By extraction with ether, fat content of feed can be approximated. The procedure also extracts other compounds present in the feed, but the magnitude of these components is generally negligible.

Ash. To determine the mineral content of feed, samples are placed in a muffle furnace and exposed to a temperature of ca. 600 °C. The material left after ignition is called the ash content. This fraction is often further analyzed for specific mineral content through such procedures as atomic absorption spectroscopy.

Crude Fiber. Because many animals have restricted capabilities for digesting fibrous materials, feeds are routinely analyzed for crude fiber. The extraction procedure produces a fraction that contains cellulose, hemicellulose, and lignin, all components not readily digested in nonruminant feeds. The Van Soest analysis has gradually replaced the crude fiber method of fiber determination. In the Van Soest analysis, feed samples are fractionated into neutral, detergent-soluble and -insoluble fractions. The soluble fraction is readily digested by most animals. The insoluble fraction is then further fractionated with an acid detergent procedure. Hemicellulose compounds are found in the soluble fraction, whereas lignocellulose (that of restricted availability) can be found in the insoluble fraction.

Nitrogen-Free Extract. This component of feed is considered to provide a crude representation of the soluble carbohydrates and nutrients not extracted by the previously mentioned procedures. It is derived mathematically by subtracting the percent moisture, ash, ether extract, crude protein, and crude fiber from 100.

In addition to the proximate analysis methods, a wide range of chromatographic, biological, and colorimetric procedures are used to identify and quantify individual nutrients in feed. *Gross energy values* of feed are routinely determined by bomb calorimetric procedures.

In vivo and in situ procedures using fistulation and cannulation surgical techniques are commonly used in experimental work to determine *digestibility* of feed components. Samples of feed are given to the animal in these evaluations, and material recovered from the stomach or intestinal regions is analyzed to see how the feed has been digested and absorbed.

6.6. Quality Control

Because feed ingredients are derived from plant sources or processing byproducts, they are inherently variable in nutrient content. Genetics plays an important role in the nutrient content of grains, as does the rate of fertilization, the climate, and the environment. Grain obtained from the same plot usually varies in nutrient composition from year to year. Additionally, mold and fungus growth is commonly found to arise from field and storage conditions. Toxins from these molds adversely affect the nutritional value of the feed.

Byproducts from industrial processing of oilseeds and rendered meat products are often highly variable, depending on the conditions and the processes used to make the primary products. Although the byproducts themselves have economic value to the manufacturer, they are not the primary products and, hence, are subject to a wide range of managerial influences.

Because of the high variability in the nutrient content of feed ingredients, feed manufacturers have developed considerable safeguards for their quality control programs. They must adhere to label guarantees of nutrient content and must demonstrate that their products are free of hazardous contaminants, such as pesticide residues or chemical contaminants.

For any quality control program to be successful, a detailed and accurate sampling program must be established. Probes are commonly used to inspect and sample dry materials, whether they are ingredients or finished feed. The size of sample, the number of samples, and the location of sampling are three primary considerations for such testing.

Devices which provide automated sampling include the bomb sampler for liquid bulk materials, diverter samplers for gravity spouts, auger samplers, and pneumatic probes [89].

With regard to actual feed or ingredient analysis, a combination of microscopic and visual inspections of products, as well as chemical assays, is routinely run for quality assurance. Microscopic analysis allows determination of the specific components of the feed source and also permits visual inspection both for mold or fungal contamination and for evidence of adulteration. Once the microscopic inspection is passed, routine chemical analyses, such as proximate analysis, are performed to verify that the product meets nutrient specifications.

6.7. Survey of Common Feeds

The profile of feed varies considerably from country to country and even from region to region within a country. Much of this variation can be attributed to the availability of locally grown or processed ingredients. In addition, governmental policies largely dictate priorities for feedstuffs. For example, corn is the most prominently used feed ingredient for animals in the United States. However, in Mexico, corn is considered to be a primary source of energy for the human population and is discouraged, therefore, from being used in animal feeds. Furthermore, governmental subsidies and tariffs play an important role in dictating availability of certain ingredients to be incorporated in feed.

All *feed ingredients* contribute a range of nutrients to the complete feed. However, ingredients are generally classified as to their respective primary contribution of nutrients, i.e., feed ingredients having high energy values are classified as energy feeds; those high in protein are classified as protein feeds. The following is a list of commonly used feed ingredients throughout the world:

High Energy Feeds
Grains: corn, barley, oats, rye, sorghum, rice, millet, and wheat (→ Cereals and Cereal Products)
Byproducts: manioc (cassava), molasses, potatoes, sugar beets, and bakery byproducts
Fats: acidulated soapstocks, tallow, and grease (→ Fats and Fatty Oils)

Protein Feeds (→ Proteins)
Oilseed meals: soybean, rapeseed, linseed, coconut, peanut, cottonseed, safflower, sesame, and sunflower (→ Fats and Fatty Oils)
Pulses: beans, chick-pea, cowpeas, peanuts, and soybeans
Meat byproducts
Poultry byproducts
Dairy processing byproducts
Marine byproducts
Nonprotein nitrogen: urea and biuret (→ Urea)
Distillers byproducts
Single-cell protein

Roughages
Hay
Silage
Pasture
Plant processing byproducts: pulp, skins, peels, and shells

Minerals

Vitamins: commercially prepared (→ Vitamins)

Feed Additives
Medications
Anthelmintics (→ Anthelmintics)
Growth promoting antibiotics (→ Antibiotics)
Hormones (→ Hormones)
Antioxidants and preservatives (→ Antioxidants)
Mold inhibitors
Flavors (→ Flavors and Fragrances)
Pellet binders
Buffers
Microbial cultures

In addition to the byproducts of food processing and the raw commodity type ingredients (e.g., grains and forages), *feed additives* are commonly used to enhance production, prevent disease, improve the commercial appeal of the product, stabilize the shelf life of the feed and improve acceptability to the animal. The list of feed additives is extremely long and varies from country to country because many countries place restrictions as to what can be added to feed, especially in the area of medications.

Table 17. Compound feed production for both developed and developing countries between 1974 and 1981 [90]

	Average production, 10^3 t/a						Growth rates

6.8. Storage and Transportation

The economics of feed production are such that transportation and storage are critical to making a profit. Because margins are relatively small on most feeds, transporting ingredients long distances is economically infeasible, especially when local products can be effectively substituted. Inventories are designed for rapid product turnover to prevent spoilage and to minimize the time raw materials and finished products are stored.

Transportation of raw materials and finished products is a function of the local/regional transportation facilities. In the Netherlands, almost all

∗∗ Mainly draught animals.

raw materials are transported by barge, and the finished products are shipped locally by truck. In the United States, raw materials are generally shipped by rail or truck, but where applicable, barge freight is used.

Another factor affecting storage and transportation is centered around whether the area uses complete feeds or uses low inclusion feeds, such as base mixes or concentrates, in conjunction with materials produced on the site of feeding (such as grain). If a complete feed is being shipped, the pricing structure is such that shipping distances must be shorter than if a low inclusion feed with higher margins is being shipped.

Because raw materials and finished products are perishable, storage is a major consideration, especially where high heat and humidity are prevalent. Environmental factors can render feed unusable in a short period when mold growth or oxidation can take place.

6.9. Economic Aspects

Growth in the worldwide feed industry is highly variable depending on respective regions. Feed tonnage in developed countries has remained relatively static resulting from slow growth in human population and leveling incomes. In rapidly developing economies, a combination of

increasing per capita income and growing human population has created new demands for livestock and poultry products.

Tables 17, 18, 19 show FAO/UN estimates of worldwide feed production and consumption for the periods from 1974 to 1981 [90]. Approximately 1.6×10^9 livestock units (1 LU = 500 kg livestock) represent the world's animal population, 80 % of which are ruminants.

1. Introduction

1.1. Food Manufacture and Preservation

In the broadest sense, the field of food technology encompasses aspects of manufacturing foods from raw agricultural materials as well as the preservation of both agricultural and industrial food products. Many *primary* and *secondary food manufacturing processes* include some elements of preservation, as in milling of grains for flour, crystallization of sugar from sugar cane or sugar beet juices, smoking of sausages, baking of bread, fermentation of grape juice for wine, and many other examples. On the contrary, the *tertiary food processing operations* are concerned mainly with preservation of both raw agricultural materials and the foods manufactured from them. The various aspects of the main food manufacturing technologies are discussed more appropriately under the various food commodity headings elsewhere in

10.1002/14356007.a11_523

this encyclopedia; more complete descriptions are given in textbooks [1–3] and other sources. This article discusses the basic principles and some industrial aspects of the main food preservation technologies applicable to many agricultural commodities and food products.

Table 1. Growth requirements for microorganisms in foods

Environmental factor	Microorganism type	General growth requirements
Temperature	psychrotrophic	will grow at refrigerated temperatures
	mesophilic	20 – 36 °C
	thermophilic	40 – 55 °C
Oxygen	aerobic	O_2 required
	anaerobic	will not grow with O_2 present
Water *	bateria	$a_w \geq 0.9$
	yeasts	$a_w \geq 0.88$ (some will grow at $a_w = 0.7$)
	molds	$a_w \geq 0.8$ (some will grow at $a_w = 0.6$)
Acidity	all	approximate range of tolerance pH 4 – 8; some yeasts and molds very tolerant to acid
Nutrients	all	wide range of specific requirements for different organisms

* Expressed in terms of water activity (a_w).

1.2. Food Spoilage by Microorganisms

Raw agricultural materials and the foods manufactured from them are composed of organic matter that is susceptible to biological transformations by various forms of microbial life. The main food components (carbohydrates, proteins, lipids, minerals, and water) are nutrients that are required not only by humans and higher animals, but by bacteria, yeasts, and molds as well. Growth of these microorganisms in the various agricultural and food products is the primary cause of food spoilage. The mere presence of microbial life in the various foods is not deleterious; however, when these mostly unicellular organisms multiply in the optimal conditions needed for their growth, food spoilage occurs. Most food manufacturing and preservation techniques (→ Foods, 3. Food Additives) are designed to produce conditions that are unfavorable for microbial growth. The main growth requirements of the various microorganisms that are important to food preservation are summarized in Table 1. More detailed information can be found in the many textbooks of food microbiology [4–7].

The common principle of food preservation by dehydration, freezing, and sterilization by heat or by irradiation, is the complete elimination of microbial growth. This does not necessarily mean elimination of the microorganisms themselves; indeed, none of these three food preservation techniques removes the microorganisms from the foods. Rather, all three preservation approaches create such conditions in the foods themselves or the environment in which the food is held as to completely arrest any possible multiplication of the microbial cells that may be present. In the case of dehydration, this is achieved by elimination of one of the main nutrients required by all microorganisms, the water. Likewise, in the freezing preservation of food, water is made unavailable to the microbial life by crystallization as ice; in addition, the temperature used for storage of frozen foods is much too low to support growth of common forms of microbial life. Only in the food sterilization processes (canning, ultra-high-temperature processing, and irradiation) are the spoilage microorganisms killed; however, even in these processes the microbial cells are not removed from the foods, and in many instances, additional precautions are necessary, such as a storage environment that is not conducive to growth of any surviving forms of microbial life (the notion of commercial sterility; see Section 4.1).

The processing conditions needed to eliminate microbial spoilage in dried, frozen, or sterilized foods are often the cause of other types of food damage and deterioration, mainly because of physical effects and deleterious chemical reactions. Thus, the final choice of a proper food preservation technology is a compromise that gives adequate protection against microbial spoilage while minimizing the physical damage and the chances for undesirable chemical reactions.

1.3. Chemical Deterioration of Food

The main components of agricultural materials and foods made from them are carbohydrates, proteins, lipids, minerals, and water. Within or outside these broad chemical groups, there are many other chemical components including vi-

tamins, enzymes, acids, dissolved gases, and other compounds, many of which can be very reactive in the conditions used for food processing and storage. The chemical changes that occur in food during processing or storage include hydrolytic and oxidative reactions of fats, enzymatic breakdown of proteins to bitter peptides, and the various forms of food browning caused either by enzymatic reactions in the presence of oxygen as in fresh fruits or vegetables or by reactions of carbohydrates with protein or other carbohydrate molecules on high heating (the Maillard reaction). Some of the most important chemical reactions deleterious to food quality are enhanced by preservation processes such as removal of moisture, freezing, or concentration of the reactive components. More detailed information can be found in various food chemistry textbooks [8–10].

For the short-term preservation of fresh agricultural produce or manufactured foods, these reactions are much less important than microbial spoilage. However, in storage of food processed by the long-term preservation technologies, these chemical reactions often become the main factor determining the specific processing and storage conditions. In particular, fat oxidation, nonenzymatic (Maillard) browning, or enzyme-catalyzed flavor changes involving various food components are typical undesirable chemical reactions associated with dried, frozen, or sterilized foods. The rate of these and other deleterious reactions often depends on the presence and the state of water in the system.

1.4. Water Content and Water Activity

The most abundant component of raw agricultural products and many manufactured foods is water. (→Foods, 1. Survey, Chap. 3.1.). Although the total content of water in a given food may be useful as an indicator of nutritive value and a determinant of the necessary processing operations, it is the state in which this water is present that affects the shelf life and the susceptibility to various microbial and chemical spoilage reactions. The most common approach used to describe the state of water in a complex food material is through the water activity of the system.

The water activity (a_w) of a given food is defined as

$$a_w = \frac{p_f}{p_w}$$

where p_f and p_w are the pressures of water vapor in equilibrium with the given food system and with pure water, respectively, both at the same temperature. Because p_f can vary from 0 (for a completely dry system) to p_w (for an infinitely diluted aqueous solution), the range of a_w values varies from 0 to 1. Examples of typical a_w values for various foods are shown in Table 2; also listed are the requirements of the main food spoilage microorganisms for a_w conducive to their growth, while the general effect of a_w on the various food spoilage reactions is shown in Figure 1.

The main factor influencing p_f is the type and the amount of substances dissolved in the aqueous phase of a food, as approximated by Raoult's law:

$$p_f = p_w \cdot \left(\frac{n_w}{n_s + n_w}\right) = p_w \cdot X_w$$

where n_w and n_s are the number of moles of water and solute in the food, and X_w is the mole fraction of water. Although Raoult's law is exact only for ideal solutions, it gives a sufficiently close approximation of water activity of many common food systems. Considering the typical mass percentages found in foods, small molecules (some salts and acids) have a much greater effect at lowering a_w than do larger solutes, such as sugars, as shown by Raoult's law. Because of their very large molecular masses, food proteins have a negligible effect on a_w even in foods with high protein content. Although the water binding property of food proteins may be important for structural aspects of food systems, the water activity of typical protein-based foods, such as meat products or most cheeses, is not very different from that of pure water. Because fat is insoluble in water, it does not participate in the a_w food interactions. More specific information on a_w in foods is available in various books [11–13] and review articles [14, 15].

Individual food components may exert different effects on a_w before, during, and after a particular food preservation process; this, in turn, determines processing conditions (or even the process suitability) for each individual food. Some a_w relationships (Fig. 1) are particularly important in the case of food drying, where the

Table 2. Approximate values of moisture content and water activity (a_w) for selected foods and growth requirements of selected microorganisms (orientation data)

Food product	Average moisture content, wt %	Water activity (a_w)	Microbial activity
Water	100	1.00	
Fresh fruits, meats, vegetables	95 – 60	0.99	many pathogenic bacteria
Bread, aged cheese, salami	50 – 40	0.95	many spoilage bacteria
Ham, processed cheese, baked foods	40 – 20	0.90	*Lactobacillus, Bacillus*, and *Staphyloccus* species
Jams, jellies, parmesan cheese	30 – 20	0.80	sugar-tolerant yeast and bacteria
Salted meat, fish, condensed milk	30 – 20	0.70	osmophilic yeast and molds
Dried fruits, candy, honey, pasta products	20 – 10	0.60	a few osmophilic yeasts and molds
Dried mushrooms, dried milk, other dried foods	8 – 2	(0.3 – 0.2)	no growth

food product typically undergoes changes spanning the complete range of a_w, often in conditions of high heat input. Careful control of a_w and its manipulation is used in other traditional food manufacturing and preservation technologies, including preparation of fruit preserves, salting of fish and red meats, or in the new technology of intermediate-moisture foods (see Section 2.6).

2. Food Preservation by Dehydration

2.1. Concentration and Drying

Because water is one of the main nutrients required by all microorganisms for their growth, water removal (dehydration) offers theoretically one of the simplest opportunities for long-term food preservation. In industrial practice, the long shelf life of dry foods is important primarily for grains and some of their endproducts (flour, starch, pasta, and breakfast cereals), other agricultural commodities with a generally low moisture content (spices, herbs, dry pulses, and other seeds), and processed foods that can be dehydrated with little deleterious effect (e.g., skim milk or coffee extract). Many agricultural commodities and food products are available in the dehydrated form (dry fruits, vegetables, fish, eggs, cheese, completely prepared meals, baby formulas, and many specialty products), although in many instances the quality difference compared to fresh foods may be substantial.

Conceptually, food dehydration describes any process resulting in removal of water from food. In industrial practice, "food dehydration" is often used to describe "food drying," i.e., almost complete removal of water from either a liquid or a solid food to obtain a product with a very low a_w. In many industrial food drying processes (especially in those used for drying liquids such as milk, coffee, or fruit juices), the drying itself is preceded by a concentration process, whereby a major portion of the water is removed from the food solution more economically and

without changing the physical nature of the material, thus maintaining its fluidity. Concentration processes are special cases of food dehydration. They are important in industrial practice, but by themselves, with a few exceptions, such as sweetened condensed milk, do not result in products with a long shelf life.

2.2. Food Concentration Technology

The traditional processes for concentration of liquid foods are based on the principle of "boiling off" some of the constituent water under reduced pressure (the term evaporation is often synonymous to concentration in these cases). The evaporation is carried out under partial vacuum to minimize heat damage to the many heat-sensitive food components and to reduce the energy needs of the process (→Evaporation). The simplest production units, the *single-effect evaporators*, are relatively inexpensive to install, but the operating costs are high and productivity is low. The latent heat requirements for the evaporation are usually supplied by condensing steam.

For higher production economy, *multiple-effect evaporators* (Fig. 2) use the water vapors produced in one evaporation stage as the energy source in the next effect after appropriate elevation to a higher energetic level by "thermocompression" (enrichment with fresh steam) or by "mechanical recompression" with a steam compressor [16]. The installation costs of multiple-effect evaporators increase with the number of stages, but the effectiveness and operation economy improve substantially. Often the vapors generated in the food concentration process carry various volatile compounds characteristic of the given food flavor; in some cases, the flavor volatiles are stripped from the vapors and returned to the finished product.

Newer food concentration processes include freeze concentration [17] (see also Section 3.6) and reverse osmosis (RO). In *freeze concentration*, the liquid product is concentrated by freezing out some of the constituent water as ice and separating the ice from the concentrate. Technical advances have resulted in significant improvements, especially in the concentrate separation from the ice crystals, a problem that has hindered a more widespread use of this quality-efficient concentration technology [17], [18]. Because vacuum is not used to remove any volatile constituents, flavor retention in the freeze-concentrated foods is high. Industrial uses of freeze-concentration technology include plants for processing fruit juices, coffee, vinegar, and liquid beer concentrate for reconstitution "on the tap."

Reverse osmosis (RO) is an example of a membrane separation process based on selective molecular transport through a filtration membrane (→Membranes and Membrane Separations) [19]. The specially constructed membranes for RO are permeable to water, but essentially impermeable to any solutes that may be present; when pressure that exceeds the osmotic pressure of the liquid is applied, the solvent water permeates the membrane, thus leaving a more concentrated solution. The uses of RO in food concentration processes include specialized application for sensitive food materials (e.g., concentration of enzyme solutions) and as a preconcentration step to increase capacity of existing evaporators.

The related *fractional concentration* or "fractionation" process of ultrafiltration (UF) is based on the same principle, but uses a much "looser" membrane, permeable to other small molecules in addition to water. Typical applications of UF are in the recovery and concentration of protein fractions from protein-containing liquids such as milk, whey, blood serum, or various plant protein extracts. The industrial uses for UF have been increasing rapidly, principally in fluid milk processing, in cheese-making [20], for recovery of various valuable food proteins and in the production of fruit juices from whole pureed fruits [21].

In many cases where long shelf life or savings in transportation costs are important, the concentrates produced by the membrane processes must be dehydrated further in a suitable concentration or drying process, as the concentration efficiencies of RO and UF are limited to ca. 20 – 30 % total solids.

2.3. General Aspects of the Food Drying Processes

The preservation principle used in the drying of foods is the creation of a very low a_w system, which will not support microbial growth. This

Figure 2. A principle of a multi-effect evaporator for concentrating liquid foods
a) Steam calandria; b) Vapor – liquid separator; c) Pump; d) Condenser

requires substantial removal of the product constituent water, often to a final moisture content $< 3-5\,\%$.

Food drying is a combined heat and mass transfer process (→Drying of Solid Materials). Heat energy must be supplied to the food to change the liquid water contained in the food to water vapor, which is subsequently removed. In most industrial food drying operations, heated air is used for both the heat and mass transfer functions; notable exceptions include roller (drum) drying and freeze drying, popular for several specialized food drying operations, as well as the seldom used vacuum drying.

Theoretically, most of the heat and mass transfer in food drying where hot air is used occurs on the surface of the food. As long as the moisture mass transfer rate from the food surface to the air is in equilibrium with the diffusion rate of moisture from the interior of the food to the surface, the drying process is said to be in the *constant rate period.* In this stage, the rate of moisture removal does not change with time and is governed by the external drying conditions (mainly the air temperature, humidity, and velocity). As a result, the temperature of the food surface is much lower than the temperature of the drying air because of the evaporative cooling effect of moisture removal. In the second drying stage, the *falling rate period*, the migration of the water from the interior to the surface is slower than the mass transfer of the water vapor to the air, and the temperature of the food rises. Table 3 lists the characteristic aspects of the constant and falling rate periods important to food drying operations. A more detailed description of food drying theory is covered in specialized texts [22], [23].

Table 3. Characteristics of the constant and falling rate periods in drying

Constant rate period	Falling rate period
Surface completely wetted	surface partly dry
No effect of material on drying rate, no effect of water diffusion through food	drying rate controlled by diffusion of water in material
Rate of diffusion is greater than rate of evaporation	rate of diffusion is lower than rate of evaporation; water may evaporate within the food
Heat transfer only between heat source and food surface	heat transfer through food may be important
Temperature of surface is approximately wet bulb	temperature of surface approaches temperature of drying air

Proper control of the air drying process, particularly in the falling rate period, is critical to the quality of the dried food product. The following quality defects [22] are common to many dried foods; in most cases, these need to be minimized by properly conducted drying processes.

Tissue Shrinkage. As water is removed in the course of drying, many foods shrink because of the elastic nature of the tissue, the surface tension exerted by the water, and the pressure difference between the outside and the voids left by the removed water. Shrinkage can be particularly severe in the case of slow drying.

Browning and Heat Damage. Many foods contain both proteins and sugars, the main reactants in the Maillard browning reaction. When heat transfer is not controlled properly, much heat damage can occur particularly in the falling rate period when a_w of the drying food may be in the intermediate zone most conducive to rapid browning (Fig. 1). Vitamin destruction, protein denaturation, and other typical heat-dependent reactions may also occur in improperly controlled drying processes.

Case Hardening. This term denotes a defect caused by a hard crust formed on the food surface, which interferes with further dehydration and which can be severely damaged by heat. As a result, the food appears to be dry while still containing substantial amounts of moisture. The defect, which may be characteristic for drying of certain foods, is often aggravated by migration of soluble constituents to the food surface together with the solvent water.

Loss of Solubility or Rehydratability. As a result of these effects (i.e., shrinkage, heat damage, and case hardening) the dry food may be difficult to reconstitute to its original state. In the case of liquid foods (milk and fruit juices), the drying effects appear as loss of solubility and formation of a sediment on reconstitution; for solid foods, reabsorption of water can be exceedingly difficult and may require up to several hours. Many air-dried foods (mushrooms, fruits, etc.) never rehydrate to their original moisture content.

Loss of Flavor Volatiles. Because drying is based on volatilization of water, other components may also be removed in the drying process. Many food flavor components are volatile, and loss of flavor is indeed one of the most common defects of all dried foods. Although many alternative designs of food drying processes have been developed to minimize other quality defects, loss of flavor is a difficult problem, often hindering wider acceptance of many industrially dried foods.

Many alternative engineering designs of basic air drying technology have been developed for foods to minimize some of these defects. In addition, food drying processes based on heat or mass transfer mechanisms other than the use of hot air have been successful in several specialized situations.

2.4. Food Drying Technology

Some of the important dry food products worldwide are milk, coffee, some vegetables (e.g. mushrooms, potatoes, and onions), pasta products, eggs, fish, meat, herbs, and spices, as well many dry food preparations for direct use by consumers (e.g., soups, gravies, condiments, complete meals for mountaineers, army rations, and baby foods) or for industrial and institutional uses (dry ingredients for the meat industry, dry cheese, and nutritional formulas for hospitals).

Different drying processes are available for drying solid or liquid foods (→ Drying of Solid Materials). The choice of a particular drying system often depends on the characteristics of the material being dried, its heat sensitivity, flavor retention properties, physical structure, designated end use, and, often most importantly, the cost of the process. Some techniques, such as freeze drying, are suitable for almost any product, but its high expense limits more widespread use; in other cases, custom-built equipment may be required for specialized applications.

2.4.1. Convection Drying

The majority of food drying technologies are based on the use of hot air for the convective heat transfer as well as for removal of the evaporated water. A great variety of batch or continuous air driers exists; most of the air drier designs vary mainly in the configuration of the drying chamber, i.e., the position or relative movement of the food and the air stream. Basic drier designs for solid food items include cabinet, kiln, tunnel, belt, tray, and other types of driers. According to the air movement, the design may by cocurrent, countercurrent, or crosscurrent. Figure 3 shows schematically several basic common air drier designs. More detailed descriptions can be found in specialized texts [22], [23].

Fluidized-Bed Drying. This is a special case of hot air drying suitable for drying of particulate foods (e.g., peas, corn, carrot cubes, and potato granules). The relatively high velocity of the cross-flow stream of air through the particulate bed provides controlled "air lift" to the

Figure 3. Principles of various air-drying processes

individual food particles, resulting in "fluidization" of the bed. Thus, more efficient drying is achieved because of increased total product surface area available to air contact. Both batch and continuous fluidized-bed driers are used (Fig. 4).

Figure 4. Principle of a fluidized-bed drier
a) Vibrating mechanism; b) Fluidized product

Spray-Drying. Although limited mainly to liquid foods, spray-drying is probably the most widely used food-drying technique. The principle of the continuous spray drying process is the dispersion (atomization) of the liquid being dried into a stream of hot air entering the drying chamber. The diameters of the individual droplets in the liquid spray are in the micrometer range and the inlet air temperature may be in excess of 200 °C; this results in almost instantaneous evaporation of the constituent water from the food particles into the air. The stream of the drying air exiting from the drying chamber carries the water vapor, absorbed from the food, as well as the dry food particles themselves. The dry food powder is subsequently removed from the air stream in a suitable powder-separation step.

Any food material that can be converted to a liquid or a slurry can be spray-dried; the resulting product is primarily a powder. The main difference between spray-drying, which is a special case of hot air drying, and other food drying processes is the relatively short drying time (several seconds) that does not allow for regulation of the drying process by time control. Because of the very rapid drying of the small droplets dispersed in the drying atmosphere of hot air, some of the

deleterious changes common to many other drying processes can be minimized.

The *basic spray-drier design* (Fig. 5) consists of three major parts: the drying chamber (a), the fluid dispersal (atomization) mechanism (b), and the dry powder collection assembly (c). The choice of atomization method influences the basic construction of the drying chamber (drying tower in the case of vertical driers). The most widely used atomization systems are the pressure nozzle and the centrifugal atomizing wheel. Whereas centrifugal atomization is much more complex and more expensive than nozzle atomization, the atomizing wheel provides greater versatility as it can handle viscous and particulate liquid systems.

Figure 5. Principle of a spray-drier
a) Drying tower; b) Spray (atomization) mechanism; c) Dry powder collection (air cyclone)

Because of the fine nature of the dry particles, the powder collection assembly must be designed effectively to minimize entrainment of the dry material in the escaping drying air. The powder collectors used most often include the dry cyclone, the "baghouse," and the agglomerating trough (see Section 2.5). The "liquid collector" assembly, sometimes installed to recover the finest particles from the exhaust air, can be a source of microbial contamination and is thus unsuitable for modern food-drying operations.

Developments in spray-drier design include multiphase drying, where the primary spray-drying phase is followed by secondary belt drying of the collected powder; incorporation of heat exchangers for heat recuperation from the exit air; and a more compact design combining the drying and collection chambers. Additional information is available in sources [24], [25].

2.4.2. Contact, Vacuum, and Freeze Drying

In several specialized food-drying processes, the necessary heat transfer to the product being dried is accomplished by means other than hot air. For atmospheric contact drying (represented by the drum-drying process popular especially in the dairy industry) the heat is supplied through a hot surface in contact with the food product, while the evaporated water is dissipated to the surrounding atmosphere. To decrease the temperature for the phase change of liquid water to vapor, drying of heat sensitive foods may sometimes be carried out under vacuum. In the absence of air as both the heat transfer and mass transfer medium, heating is accomplished by contact with heated shelves or by radiation, whereas the water vapor removal requires vacuum pumps, refrigerated condensers, or other complicated designs.

Drum-Drying. For drying liquid or slurried products where heat damage is not detrimental, drum (roller) drying offers an economical alternative to spray-drying (for an example of a drum drier, see → Drying of Solid Materials). Water removal occurs typically at atmospheric pressure (vacuum drum driers have not been successful) by spreading the liquid being dried onto the surface of slowly rotating stainless steel rolls filled with saturated steam. After a full revolution of the drum, the sheet of dry material is scraped off the surface just before it reaches the area where the liquid is applied. Drum drying can be used in some specialized applications, such as for milk drying for confectionery use or for lower value inexpensive products (feed mixes, waste products from potato processing, etc.)

Freeze-Drying. The principle of freeze-drying (lyophilization) is the removal of water from frozen food by sublimation. Because the food is held in a solid state during the whole drying process, shrinkage is avoided; thus, the dry products are easily rehydratable. However, a similar fast rehydration effect has been achieved

with mushrooms using simple high vacuum drying [26], thus indicating that the need for prior freezing followed by sublimation drying may not be necessary in all cases, especially for delicate products where freezing results in substantial textural damage (see Section 3.4).

The need for controlled heat application in the freeze-drying process (to avoid melting the ice during drying) results in little heat damage, but requires long drying times under high vacuum, the main cost factor in this very expensive process.

Whereas retention of flavor in freeze-dried foods has been cited as a significant advantage over other food dehydration technologies, variable flavor losses may still occur, primarily because of the high vacuum needed for the sublimation. Because of the absence of air, heat transfer must be accomplished either by conduction from the heated shelves through the poorly conducting dry layers of the food to the frozen core, or by radiation, which may cause heat damage to the dry outer layers (Fig. 6). As a result, processing costs are high, and the freeze-drying process is used only in specialized applications involving foods of high value (e.g., coffee or functional food protein preparations) or for unique requirements such as lightweight rations for mountaineers, backpackers, or explorers.

Figure 6. Illustration of the heat transfer processes in freeze-drying
a) Heated shelves; b) Dry food layer; c) Frozen food core

2.4.3. Radiant-Heat Drying

Use of radiant-heat transfer for the drying of foods is not common. The only two examples of practical significance are the radiant-heat supply in some cases of freeze-drying and the traditional drying of food materials by exposing them to the effects of the hot sun.

Sun Drying. Leaving food in the sun to dry was the original food preservation technique used by ancient Egyptians, as well as by North American Indians. Despite significant technological developments, sun drying of food is still an important technique used in many countries and in specialized situations (production of raisins, dried fish, dates, household drying of wild mushrooms, and other items). A new meaning of the term "sun drying" may be emerging with the development of driers for delicate products requiring low heat input (e.g., hops and mushrooms); in these driers, solar heating is used to heat the drying air, which is then conveyed to a modern drying chamber. The main problems of traditional, open air sun drying are the fluctuating supply of the heat, which is dependent on weather conditions and the time of the year, as well as proper hygienic control of the drying process.

2.5. Instantization

Spray-dried powders produced from liquid foods (e.g., milk, coffee, and chocolate) often show poor water-reconstitution properties, resulting in the formation of clumps. This defect is usually related to the very small particle size of the powders produced by the spray nozzle or atomizing wheel mechanisms. The poor ability of otherwise soluble powders to be reconstituted can be improved by using an instantization process, whereby the surface of the individual small particles is partially wetted in an atmosphere of moist steam in agglomerating chambers or "troughs." The particles are allowed to form loose aggregates, which are subsequently redried, thus creating large porous agglomerates that can be readily stirred into water during reconstitution.

2.6. Moisture Sorption Isotherms of Foods

The main requirement for successful food preservation by dehydration is sufficient lowering of a_w to prevent microbial growth. However, the final moisture content to which a food is dried is an important quality determinant of the dried product. Drying to a minimum moisture content

may not be possible and is not always desirable. A low moisture content in some foods may lead to oxidation of fat, whereas in other foods the same moisture content gives the longest shelf life. The optimum moisture content of dried food can be determined from experimentally established relationships between the moisture content and the corresponding water activity, known as moisture sorption isotherms (Fig. 7). Each food, depending on its particular composition, shows a different sorption isotherm [27]. Comparison of sorption isotherms for the same fresh foods and foods previously dried (desorption vs. adsorption) often shows a phenomenon of sorption hysteresis (area a, Fig. 9). The difference in the amount of moisture giving the same a_w for fresh versus previously dried foods is related to the food structure and its damage in the drying process, the affinity of water for the various food components, and other effects. For the longest shelf life, different foods require drying to a different optimum final moisture content, which can be determined by the classic Brunauer, Emmett, and Teller (BET) technique [28] or by similar more accurate modern procedures [29], [30]. In general, the optimum final moisture content of dried foods is in the vicinity of a theoretical value corresponding to a monomolecular layer of water molecules bound to all reactive sites of the food. Typical moisture contents and monomolecular layer values for several dried foods are as follows (in wt %):

Potato flakes	6.51
Freeze-dried salmon	6.84
Onion powder	3.58
Spray-dried cheese	2.22
Freeze-dried whey protein	8.03
Dried beans	4.50

Although the shelf life of dried foods is generally measured in months or years, the main quality determinants of properly dried and packaged foods are the deteriorative chemical reactions caused by removing water from the system.

2.7. Intermediate-Moisture Foods

With a few exceptions, dried foods are unsuitable for direct consumption without reconstitution with water. The low moisture content of dried foods makes them hard, brittle, and difficult to chew. A new technology of intermediate-moisture foods (IMF) was developed during the manned moon-exploration activities (1960 – 1970) to overcome the need for water to reconstitute dried foods while maintaining the sufficiently low a_w needed for preservation without refrigeration. Because microbial growth generally does not occur below $a_w = 0.6 - 0.55$, foods formulated to this a_w range may be stored without refrigeration or other special preservation techniques. The moisture content of these foods is usually high enough to ensure acceptable sensory properties, including chewability, not encountered in most dry foods.

Figure 7. Moisture sorption isotherms for foods
a) Sorption hysteresis loop; b) Desorption (fresh food); c) Adsorption (dry food)

The concept of IMF is not new; jams, jellies, fruit cakes, some dry sausages, or even pemmican, the traditional food of American Indians, are examples of ready-to-consume foods that need not be refrigerated, yet do not spoil because of their low a_w. Modern IMF technology is based on the use of various food-grade, water-soluble compounds that lower a_w when added to a food. Some a_w-lowering compounds, generally known as *humectants*, have a long history of traditional use for food preservation (especially salts and sugars), whereas others (e.g., glycerol and sorbitol) are common food ingredients now being used for purposes other than a_w control. Alternative technological processes used include partial drying, infusion of dried foods with a liquid mixture of humectants, or careful formulation of ingredients according to the Ross equation [31]:

$$a_w\,(\mathrm{f}) = a_w\,(1) \cdot a_w\,(2) \cdot a_w\,(3) \ldots a_w\,(n)$$

where a_w(f) is the final a_w desired and $a_w(i)$ are water activities of binary solutions of the

same concentrations. Although minor discrepancies often exist between experimental values and those predicted by the Ross equation, for many routine industrial applications the use of this empirical equation is satisfactory.

Uses of IMF technology are limited to a few special applications including pet foods and granola-type breakfast bars. The main limitation is the need for relatively large amounts of humectants to achieve the required a_w lowering, which results in undesirable sensory impact.

3. Food Preservation at Low Temperature

3.1. Refrigeration and Freezing

Food preservation by cooling is the most common technique used for food storage in all parts of the world. In industrialized countries, widespread use of mechanical refrigeration gave cold temperature preservation its prominence as the principal short-term food preservation technique for fresh foods in households as well as in industrial processing and retailing.

As long as foods are held at storage temperatures above their freezing point, no phase change in the constituent water occurs, and some of the cold-tolerant microorganisms (psychrotrophs) can grow. Thus, cold storage without freezing retards but does not stop the food spoilage process. For a long-term effect, food preservation by low temperature must include freezing and frozen storage. In frozen food, most of the water is present as solid ice and this makes it unavailable to support microbial growth. With the very low temperature of frozen storage, which further inhibits any biological activities, food freezing offers a much longer shelf life than can be achieved with cold storage above the freezing point. However, freezing does not destroy microbial life; after thawing, frozen foods are just as perishable as fresh foods. Some psychrotrophic bacteria can grow at temperatures as low as −5 to −10 °C; thus, since not all water is frozen in foods stored close to their freezing point, slow microbial growth can occur in improperly stored frozen foods.

3.2. General Aspects of the Food Freezing Process

Whereas pure water freezes at 0 °C, the freezing points of foods depend on the amounts of solutes dissolved in their constituent water (see Raoult's law, Section 1.4). Typical *apparent freezing points* of various foods are as follows:

Vegetables (e.g., peas, cauliflower, onions, carrots, and tomatoes)	−0.9 to −1.4 °C
Fruits (e.g., pears, plums, and apricots)	−1.8 to −2.5 °C
Berry fruits (e.g., strawberries and raspberries)	−0.8 to −1.2 °C
Milk	−0.5 °C
Beer	−2.2 °C
Meat, poultry, and fish	−0.6 to −2.0 °C
Ice cream	−4.0 to −6.0 °C

An approximate freezing point (t, in °C) of a solution of given molality M can be calculated as

$$t = -1.86 \cdot M \cdot n$$

where n is the number of ions or particles formed by dissociation of the solute molecules.

As a result of the freezing process, pure *ice crystals* are formed in food placed in a cold environment. The size, amount, and location of the ice crystals depends on the rate of the heat transfer from the food to the environment; the rate, in turn, is determined by the temperature difference between the apparent freezing point of the food and the environment temperature and

also the heat transfer coefficient characterizing the freezing process used. Faster freezing rates result in larger amounts of smaller crystals and a more uniform distribution of them. In biological materials where preservation of viability is important (frozen spermatozoa or embryos, red blood cells, organs for transplant operations, or microbial cultures for dairy and other food industries), the position of the formed ice crystals is of great significance. Appearance of ice crystals within the individual cells, resulting from very fast freezing rates, usually causes loss of viability; however, for optimum frozen food quality, the fastest possible freezing rate is normally preferred.

The *time – temperature profile* of a food frozen at two different rates is shown in Figure 8. At a slow freezing rate, the food temperature remains constant near its freezing point as all the heat removed is the latent heat of solidification. Ice crystal formation is slow, and a smaller number of larger crystals are formed, in contrast to a fast freezing rate, which favors crystal formation rather than crystal growth. In the freezing of fruits, vegetables, and other foods with recognizable cellular structure, slow freezing favors extra-cellular crystal formation. Migration of water to the growing crystals from the interior of the cells produces highly concentrated unfrozen solutions of salts, organic acids, and other component solutes within the cell. This, together with the volume increase after freezing (caused by the 9 % volume difference between liquid water and ice), may lead to severe textural damage in those products where the cell walls and membranes provide the structural network. On the contrary, rapid freezing may result in intracellular freezing, which affects the viability of the biological cell but does not necessarily affect individual cell integrity. However, volume changes may be important in products with a high moisture content because they produce cracks throughout the tissue. A generalized view of the two opposing effects on final viability of a biological cell is shown in Figure 9. Although this theoretical representation has been confirmed experimentally for the viability of various tissues [32], its importance for frozen food quality remains to be established. In general, the study of the food freezing process and of its effects on food quality is difficult because effects of freezing, frozen storage, and thawing cannot be easily separated. However, much theoretical and practical information is available on the various technological aspects of the frozen food industry [33], [34].

a) Net survival rate; b) Intracellular freezing; c) Solute effects

3.3. Food-Freezing Technology

Although many different engineering process designs have been developed for freezing food, they are all based on the same principle of placing the food in contact with a cold environment. The cold is generated either by a mechanical refrigeration system or by the use of liquefied gases with low boiling points (usually below −100 °C) (→ Cryogenic Technology, → Refrigeration Technology). Mechanical refrigeration systems are most often based on repeated use of ammonia either with a compressor or in an absorption system. In both cases the systems are operated in a closed cycle as ammonia is toxic, and thus an indirect means of heat transfer from the food to the ammonia must be accomplished: either through cold air, a cold liquid such as salt brine or alcohol, or a cold solid surface. On the contrary, cryogenic freezing systems using N_2 or CO_2 are operated in an open cycle, and the heat transfer from the food to the liquefied cryogenic gas is direct.

Table 4. Classification of freezing processes

Process	Frozen front movement, cm/h	Temperature change within food, measured in
Slow	0.1 – 0.2	°C/h
Intermediate	0.2 – 0.5	
Fast	0.5 – 3	°C/min
Very fast	3 – 10	°C/s

One of the principal differences distinguishing the various food freezing systems is the freezing rate achievable. On the recommendation of various bodies, such as the International Institute of Refrigeration (IIR), the freezing processes can be classified as slow, intermediate, fast, and very fast according to the velocity of movement of the frozen front from the surface to the thermal center of a product (Table 4). Alternatively, freezing velocity can also be defined as the change of temperature in the food per unit time.

Figure 10. Principle of air-blast freezing tunnel
a) Insulation; b) Conveyor; c) Air fan; d) Air intake; e) Air cooling

3.3.1. Convective Processes

Still Air and Blast Freezing. Cold air at −10 to −40 °C is the most commonly used medium for freezing foods. The simplest freezing method (still air, also sharp freezing) consists of placing the food material in an environment of stagnant cold air, as practiced in typical household freezers. This is the least efficient freezing method, resulting in long freezing times, very slow freezing rates, and the most damaging effects on food structure due to formation and growth of large ice crystals. Still air technology is used industrially for storage of frozen foods; however, freezing is usually accomplished by a different means.

Movement of the cold air around the foods being frozen increases freezing rate. Air blast tunnels (Fig. 10) are commonly used for freezing small size food products, such as ice cream, fish, french fries, fruits, seafood, etc; typically, the product is carried through the tunnel on a conveyor (b) in a countercurrent or crosscurrent arrangement relative to the high velocity (3 – 10 m/s) stream of cold (−10 to −30 °C) air. Freezing in air blast tunnels is efficient and economical; however, for improperly packaged foods blast freezing may cause excessive dehydration, resulting in fresh weight losses and need for frequent defrosting of the freezing equipment.

Fluidized-Bed Freezing. In a manner similar to fluidized-bed drying (see Section 2.4.1), small particulate foods can be frozen by a stream of cold air passing through a stationary or moving bed of the material being frozen. The air-lift effect of the cold air results in improved contact of the air with the food surface, thus increasing heat transfer and correspondingly the freezing rate. Because of the rapid freezing rates, moisture losses can be lower than in comparable blast freezing operations. Fluidized-bed freezing is particularly suitable for products of uniform size and high commercial value (e.g., shrimps and blueberries).

Immersion Freezing. For limited industrial applications, nontoxic liquids with a low freezing point are being used for freezing packaged or unpackaged foods by direct immersion. This method is sometimes used for freezing fowl, tightly packaged in thin plastic film; the rapid surface freezing of the submerged poultry results in the attractive, uniform white appearance of the finished package. The heat-removal bath may be a cold (−10 to −20 °C) aqueous medium containing a water-miscible material (ethanol, propylene glycol, or glycerol), resulting in substantial freezing point lowering, or the bath may be an aqueous salt solution (sodium or calcium chloride), a nontoxic freezing agent (freon), or a liquefied gas such as nitrogen or carbon dioxide. However, use of a liquefied gas for immersion freezing is not practiced industrially; rather, these gases are used as sprays in cryogenic freezing tunnels.

3.3.2. Cryogenic Freezing

See also → Cryogenic Technology. The use of liquid nitrogen or liquid carbon dioxide is advantageous for attaining very fast freezing rates, for infrequently used small installations, or for mass production of specialized products in dedicated

freezing lines. The principal difference distinguishing cryogenic freezing from other food freezing methods is the direct contact of the food with the primary freeze-producing agent (N_2 or CO_2), which undergoes a change of state. Because of the low boiling points (−196 °C for N_2, −78.5 °C for CO_2 at 100 kPa), both the latent heat of vaporization and the sensible heat removed by the cold gas contribute significantly to the fast heat transfer from the food being frozen. Typically the basic design of a cryogenic freezer installation consists of a conveyor for the food to be carried under the cryogenic liquid spray in a simple insulated tunnel (Fig. 11); the cold gas escaping through the tunnel both concurrently and countercurrently with the conveyor movement provides either the precooling of the fresh material or the postfreezing heat removal from the frozen product.

Figure 11. Principle of a cryogenic freezing tunnel
a) Insulated tunnel; b) Conveyor belt

The main *advantages* of cryogenic freezing systems are the very fast freezing rates, resulting in superior quality of most frozen food products, the very low weight losses because of negligible evaporation of water, and the low cost of the freezing equipment installation. The main *disadvantage* is the high overall processing cost, resulting from the high cost of the nonrecoverable freezing agent; in addition, the special safety precautions needed for installation and handling of hazardous compressed gas materials and equipment on otherwise nonhazardous industrial premises may discourage many potential applications.

3.3.3. Contact Processes

Plate and Scraped Surface Freezers. The principle of these processes is heat transfer from the food through a cold stainless steel surface. Rectangular packages (e.g., ice cream cartons, boxed vegetable products, and blocks of fish) can be frozen by contact freezing between two plates in plate freezers (Fig. 12). Either cold salt brine or other liquid freeze-producing agents (ammonia or freons) may be used for cooling the plates of the freezer. These often fully automated multiplate machines are popular because they require little floor space, have high loading capacity, and are effective for freezing prepackaged goods. However, the typical paper packaging used for the rectangular containers being frozen constitutes a hindrance to the required heat transfer so that the achieved freezing rate is not particularly fast, especially for foods containing large voids.

Figure 12. Principle of a contact plate freezer
a) Freezing plates; b) Plate compression mechanism; c) Food product

Much more effective freezing can be accomplished in contact freezing of unpackaged goods, such as fruit juices, freezer jams, or ice cream in scraped-surface continuous freezers (Fig. 13), where freezing occurs on the inside surface of a barrel cooled by a proper liquid coolant (ammonia, freon, or brine). The continuous scraping of the surface by rotating blades usually results in the incorporation of some air; this is often desirable as the semifrozen paste must possess enough flowability for effective product movement through the machine.

In the manufacture of ice cream products, the scraped-surface ice cream freezer is used for pro-

duction of the semifrozen (soft serve) ice cream mass. This may be further solidified by filling into stainles steel forms submerged in cold liquid (on-stick novelties) or into other suitable containers (boxes, cones, biscuit sandwiches, and cups), which are then "hardened" in blast or other type freezers.

Figure 13. Principle of a scraped-surface food freezer
a) Surface scraping blades; b) Outer jacket filled with coolant

3.3.4. Freezing System Capacities

The theoretical freezing capacity of the various technological equipment designs is related to the primary capacity of the cold generating unit used for removal of the latent heat of fusion from the food. The capacity of the mechanical compressors used in most freezing systems is usually expressed in practical units referred to as a "ton of refrigeration"; this is defined as the rate of heat transfer provided by melting 1 short ton (2000 lb) of ice in 24 h; thus, in SI units, a ton of refrigeration represents a rate of heat removal equivalent to 210 kJ/min. The actual rate of a food freezing process is dependent on the total heat-removal requirement (determined by the mass and the composition of the food), and on the heat-transfer properties in the system, affecting the achievable freezing time.

Heat-Removal Requirements. The total amount of heat to be removed by the freezing equipment consists of three separate segments: (1) the sensible heat change needed to cool the food to its freezing point, (2) the latent heat of fusion evolved in solidifying the liquid water in the food to ice, and (3) further sensible heat change to cool the frozen piece to its final exit temperature. Estimates of the heat removal requirements Q (in kJ) can be obtained by using the basic calorimetric energy balance approach and by assuming that all water in the food freezes at a single freezing point:

$$Q = mc_p \Delta t + mL + mc'_p \Delta t'$$

where m = mass of food, kg; c_p and c'_p = specific heats of the unfrozen and frozen material, kJ kg^{-1} °C^{-1}; Δt and $\Delta t'$ = the temperature difference for the unfrozen and frozen material (from the initial temperature to the apparent freezing point and from the freezing point to the final exit temperature, respectively), °C; and L = latent heat of fusion of the food (kJ/kg). Whereas the proper values of c_p, c'_p and L for some foods can be found in the literature [35], [36], they are determined to a large degree by the water content of the product being frozen. Satisfactory estimates of the c_p and c'_p values can be made if the weight fraction of water in the product (w) is known, using the following relationships [36]:

$$c_p = 4.2w + 0.84\,(1-w)$$
$$c'_p = 2.1w + 0.84\,(1-w)$$

(alternatively for a product with a high moisture content, $c'_p = 1/2\, c_p$ may be used, as for water) and

$$L = 335\text{W}$$

Because in reality the constituent water in a food freezes over a range of temperatures, a more accurate approach to determining heat-removal requirements is based on *total enthalpy changes.* In this concept, −40 °C is used as a reference temperature, and the enthalpy (total energy content) of all foods at −40 °C is arbitrarily taken as 0 kJ/kg; the total amount of heat to be removed Q (in kJ) is then simply obtained as

$$Q = \Delta H = H_1 - H_2$$

The appropriate enthalpy values H_1 and H_2 (corresponding to the initial and final temperatures of the food at the beginning and the end of the freezing process) need to be known for each specific food. Some numerical data are available in the literature [35]; enthalpy – H_2O concentration diagrams for a few specific food materials can also be found [35].

An *example* of using such a diagram is shown for lean beef in Figure 14. The enthalpy difference ΔH can simply be read on the y-axis for a given moisture content (74 wt % is shown in this example) between any two temperatures of interest (e.g., for the freezing process beginning at +5 °C and ending at −25 °C, the total heat to be removed is ca. 275 kJ per kilogram of meat). In addition, information about the proportion of the total water existing as ice at each particular temperature can be read off the diagram as the intersect of the vertical composition line with the α-lines giving the wt % of water frozen. In this example, the beef with 74 wt % moisture starts to freeze at ca. −1 °C; at −2 °C, ca. 50 % of the constituent water (i.e., $0.5 \times 0.74 = 0.37$ kg of water per kilogram of meat) is in the form of ice, whereas at ca. −25 °C practically all the freezable water of the meat is solidified. The remaining 12 wt % water can be considered as unfreezable water, because it is tightly bound to the protein of the meat.

Information about the percent of frozen water contained in these diagrams can be useful also for estimating temperature fluctuation effects in frozen storage. Some foods can suffer severe quality changes due to recrystallization of the water melted by a slight temperature increase followed by a decrease in improperly controlled storage equipment.

Determination of the total heat-removal requirement is important for selecting appropriate freezing equipment. However, the food freezing capacity of a system also depends on the type of food, its composition and physical properties, the shape in which it is packaged, and the properties of the packaging material, and the heat transfer properties of the system used, resulting in substantial potential variations of freezing capacities of the same system for different foods. The main determinant of the freezing capacity is the time needed to accomplish the required freezing process, which must be found experimentally or calculated by using various approximations.

Prediction of Freezing Times for Foods. Because of the nonsteady state of the freezing process and the compositional changes occurring during freezing, which result in constantly changing theoretical freezing points, an exact mathematical model for calculation of freezing time is not available. Various predictive approaches for determining the industrially important freezing time data have been developed. The most commonly used formula is *Planck's equation* for prediction of freezing time (t_f) for rectangular and other simple geometrical objects:

$$t_f = \frac{\varrho \cdot \lambda}{\theta_f - \theta_e} \left(\frac{P \cdot a}{h} + \frac{R \cdot a^2}{k} \right)$$

where θ_f = apparent freezing point of the food, °C; θ_e = temperature of the freezing medium, °C; ϱ = product density, kg/m^3); λ = latent heat of fusion, J/kg; a = characteristic dimension (thickness of slab, diameter of sphere or cylinder), m; k = thermal conductivity of frozen material, W m^{-1} °C^{-1}; h = surface heat transfer coefficient, W m^{-2} °C^{-1}, determined by the freezing process used (Table 5); and P and R = constants for material geometry, determined from Table 6 or Figure 15.

Table 5. Approximate values of surface heat transfer coefficients h for various food freezing processes

Freezing process	h, W m^{-2} °C^{-1}
Still air	6 – 9
Air blast	18 – 30
Contact plate	120
Liquid immersion	600

Table 6. Constants P and R for Planck's equation for prediction of freezing times of basic geometrical forms

Constants	Geometrical form		
	Semi-infinite slab	Cylinder	Sphere or cube
P	1/2	1/4	1/6
R	1/8	1/16	1/24

Modifications of Planck's equation have been reviewed [37]. Because the assumptions used in Planck's equation result in underprediction of freezing times by 10 – 40 % [37], many of the alternative approaches aim to improve prediction accuracy. However, most of the formulas include additional terms and constants, resulting in rather complex computational requirements, especially for other than simple geometrical shapes. In practice, the freezing time required for food is usually determined empirically, using existing equipment; however, for design purposes, freezing time calculations must often be made.

Figure 14. Enthalpy – H_2O concentration diagram for lean beef ∗
∗ = % Total water frozen as ice.
∗∗ Encircled points are used as examples in the text for beef at 74 wt % H_2O.

3.4. Effects of Freezing on Foods

Besides the main effect of freezing on food texture (see Section 3.2), freezing can result in many other important changes in foods and agricultural materials. Generally, foods can be classified in four broad groups according to their response to the freezing process:

1) Foods that can be frozen without major difficulties, e.g., bread and other bakery products, apple sauce, fruit juices, as well as the various frozen desserts based on ice cream, which is a food specifically formulated to withstand freezing.
2) Foods that need to be carefully processed to avoid problems in freezing, e.g., soups, gravies, other food emulsions, ready-to-serve frozen entrees, and certain fresh meats; without certain precautions, these foods can undergo deleterious changes resulting from the freezing process itself.
3) Foods that can be frozen without major difficulties but which will deteriorate in frozen storage; e.g., frozen fish, poultry, or certain formulated meat products may deteriorate as a result of fat oxidation or chemical changes in the protein structure.
4) Foods that cannot be processed by freezing without permanent quality changes, e.g., most fresh fruits, particularly those with a delicate texture such as strawberries or raspberries, lettuce, some cheeses, and beer.

In freezing fresh meats, care must be taken to avoid freezing during rigor mortis because, after thawing, the meat shows considerable and permanent toughening caused by the phenomenon of thaw rigor [38]. Meat frozen before rigor mortis sometimes does not experience this major defect; however, the safest practice is to freeze postrigor, well-aged muscle.

Cryoprotectants. A concept of cryoprotective additives or cryoprotectants has been introduced in cold temperature biology and medicine to minimize undesirable effects of freezing [32],

[34]. Dimethyl sulfoxide (DMSO) is an example of a cryoprotectant being used by cryobiologists because of its significant effect on freezing point lowering, thus effectively permitting cold temperature storage of biological materials without the damaging effects of ice crystal formation. Whereas DMSO is not an approved food material, the use of sugar for freezing strawberries, raspberries, and other delicate fruits is based on the same general concept. Discovery of other food-approved cryoprotectants could significantly increase the applicability of freezing to other fresh foods. An ideal food-grade cryoprotectant should be nontoxic, fully miscible with water, and easily penetratable through the cell walls and membranes, because its primary functions are to lower the freezing point, to dilute the "corrosive" concentrated solution inside the cells, as well as to minimize cell shrinkage by filling the voids left by the water deposited on the ice crystals once the freezing process begins.

Figure 15. Material geometry constants for a brick-shaped object ∗ for the Planck's freezing times equation
∗With dimensions $a \cdot b \cdot c$, where a is the thickness (shortest side).

3.5. Frozen Storage and Thawing

In addition to the various effects of the freezing process, the quality of frozen foods can be altered by the frozen storage or by the thawing regime used. Major changes can occur on *extended storage of frozen foods* including loss of protein solubility, oxidative reactions of fat, or various enzymatic reactions if the enzymes were not properly deactivated before freezing. Because some of the constituent water remains unfrozen at conditions common to frozen food storage, some chemical and enzymatic reactions occurring in the unfrozen solution can be accelerated as a result of the concentration effect [34], particularly if the temperature of the frozen storage increases suddenly. Fluctuations in storage temperature, occurring commonly in industrial or household conditions, can have a profound effect on changes in crystal size distribution throughout the food. Increased temperature causes a certain amount of melting, especially of the smallest crystals. When followed by a temperature drop, repeated freezing subsequently favors growth of larger crystals.

Frozen storage of improperly packaged food can result in drying of the food surface, creating the industrially important *freezer burn.* This is caused by sublimation of the frozen water from the surface layers, resulting from the temperature difference between the food and the coldest spot in the frozen storage, i.e., the coils of the freezing agent evaporator of the mechanical refrigeration system. As a result, the coils become covered with an increasingly thicker layer of ice, which decreases the efficiency of the cold storage, thus necessitating periodic defrosting.

Further damage to frozen food quality can be caused by an improperly conducted *thawing process.* Because of the four-times lower thermal conductivity of liquid water as opposed to ice, thawing by contact with the outside environment is slower than freezing under otherwise equal driving force conditions. Acceleration of thawing by warm air (as in defrosting at room temperature overnight) may cause rapid growth of microorganisms on the surface layers of the thawed product, while hindering reabsorption of thawed water, thus creating the unsightly and often nutritionally wasteful drip loss. The use of microwave energy, which is not transferred by conduction through the thawed food layers, is the fastest and probably least damaging thawing process.

3.6. Freeze Concentration and Freeze Texturization

Freeze Concentration. Besides the primary use as a long-term preservation technology, the

freezing process can be used in other areas of food processing. Freeze-concentration technology was mentioned briefly in Section 2.2 as one alternative for liquid-food concentration. The freezing out of water and subsequent removal of the ice crystals from heat-sensitive solutions have been accomplished in various industrial or pilot-plant designs (Fig. 16); the practical use of the concept has been limited in the past by high loss of concentrated solution in the ice crystal removal step. For efficient concentrate removal in the wash columns or other devices used, large enough ice crystals must be developed to permit effective separation.

Figure 16. Principle of a freeze-concentration system
a) Expansion vessel; b) Scraped-surface cooler; c) Pumps; d) Ice crystallizer; e) Wash column; f) Ice melting

Freeze Texturization. Freezing of proteinaceous slurries and gels may result in formation of a fibrous structure as a result of controlled ice crystal development. The concentration of the unfrozen protein slurry by ice crystals unidirectionally grown in the proteinaceous matrix may cause formation of a rigid protein network resembling meat muscle or other fiberlike structure; when freezing is multidirectional, a spongelike structure may result as in the traditional Japanese process of tofu freezing to produce a modified "kori-tofu" product. Although the scientific explanation of the freeze texturization process is still incomplete, research has resulted in several patents and much new information [39]. The freezing process itself is not sufficient for long-term preservation of the protein texture, which must often be permanently stabilized by dehydration with alcohol or by heating the thawed protein matrix.

4. Food Preservation by Heating

4.1. Pasteurization and Sterilization

Microorganisms in their various biological forms are sensitive to elevated temperature. Growth of vegetative microorganisms in foods ceases at temperatures >45 °C, as evidenced by the common practice of "hot counters" used by fast-food service establishments; prolonged exposure to temperatures above 62 – 65 °C is lethal to most viable microorganisms. Although heating of many foods is practiced for reasons other than to retard their spoilage, all processes using heat, such as boiling, frying, stewing, smoking, or baking, result in foods with extended shelf lives. The vegetative cells of the main pathogenic organisms that may be associated with foods (several species from the genera *Salmonella, Staphylococcus, Clostridium, Lysteria*) are not very resistant to heat and are killed by short heating at temperatures above 72 – 75 °C. This principle (first discovered in 1864 by the famous French microbiologist Louis Pasteur, 1822 – 1895) is the basis of *pasteurization*, a controlled heating process used to eliminate any dangerous pathogens that may be present in milk, fruit-based beverages, some meat products, and other foods which are commonly subjected to this treatment. A similar controlled heating process, referred to as *blanching*, is used in the processing of fruits and vegetables; its main purpose is to deactivate the many enzymes present in the plant materials belonging to this food category. Both pasteurization and blanching are based on the use of the minimum heat requirement needed to deactivate specific microorganisms or enzymes, thus minimizing any quality changes in the foods themselves.

The effectiveness of controlled heating processes can be increased by prolonged treatment or by increasing the treatment temperature; however, increasing the severity of the treatment may have a negative effect on some food quality parameters such as flavor, texture, or content of heat-labile vitamins. Typical time – temperature combinations used by the food processing industry are shown in Table 7. In general,

pasteurization and similar processes prolong the product shelf life especially in refrigerated storage, but do not result in shelf-stable products because many heat-resistant spoilage microorganisms can survive the heating conditions employed.

Table 7. Examples of heat treatment combinations used in food processing

Process	Heating temp. holding time	Use
Bulk liquid pasteurization	63 °C/30 min	Vat pasteurization of milk
High-temperature – short-time pasteurization (HTST)	72 °C/15 s	Continuous pasteurization of milk for safety
Ultrapasteurization	138 °C/2 s	Pasteurization of milk for extended shelf life
Cooking of meat products	to 65 – 75 °C internal temperature	Ready-to-eat products (ham, meat loafs, frankfurters, etc.)
Blanching of vegetables	variable (e.g., 75 °C/5 min)	Enzyme deactivation, tissue softening
In-bottle pasteurization	60 °C/10 min	Shelf-life extension of beer

For long-term preservation of foods by heating, the treatment used must be severe enough to destroy all forms of microbial life that could be activated in the processed foods during prolonged storage. Whereas heat-treated shelf-stable foods are often referred to as sterile, a more appropriate term used by the industry is *commercial sterility*, denoting the absence of microbial growth in the processed foods in commercially achievable handling and storage conditions, rather than total absence of any evidence of microbial life in laboratory tests.

The main difference between pasteurization and sterilization treatments is the need to deactivate the bacterial spores. These sometimes very heat-resistant dormant forms of certain types of bacteria can germinate in improperly sterilized foods, causing rapid outgrowth of the viable cells thus formed.

4.2. Theory of Microbial Deactivation by Heating

4.2.1. Heat Resistance of Microorganisms

The basis for design and conduct of the various heat preservation processes are the experimentally determined and theoretically generalized thermal destruction relationships for the various microorganisms of interest. The data obtained from thermal destruction experiments indicate that heat deactivation of microorganisms generally follows *first-order reaction kinetics*, the rate of thermal deactivation being proportional to the concentration of the microorganisms present:

$$\frac{dc}{dt} = -kc$$

where c is the concentration (usually expressed as the number of organisms per gram or milliliter of food) and t the heating time at a given temperature. Thus, the time of a heating process required to deactivate a certain proportion of the microbial population present initially (c_0) is obtained as

$$t = D \log \frac{c_0}{c}$$

where D is a death rate constant referred to as the decimal reduction time (DRT), i.e., the time needed to accomplish a tenfold (1 log cycle or 90 %) reduction of the microorganisms present (Fig. 17 A).

For a given microorganism, different *reaction temperatures* result in different D values; as shown experimentally, the effect of temperature on the D value can also be generalized by a first-order line, as shown in Fig. 17 B. This plot, referred to as thermal death time (TDT) curve, is of fundamental importance for all calculations required for thermal deactivation of microorganisms in foods. The slope of the TDT curve indicates the sensitivity of the given microorganism to temperature changes; the steeper the TDT curve, the more sensitive the organism is. The negative reciprocal of the slope, referred to as the z value, gives the temperature interval for a tenfold change in the D value. All points along the TDT line for a given microorganism represent time – temperature combinations of equal lethal effect.

The heat resistance of microorganisms (as well as of enzymes, vitamins, and other heat-sensitive food chemical components) is adequately characterized by the *D and z constants*. The typical D value given in literature is for processing at the reference temperature of 121.1°C or 250°F, denoted as D_0. The D_0 and z values are different for the many microorganisms of

importance in canning, as shown in Table 8. For heat processing of shelf-stable foods, the thermophilic spore-forming spoilage organisms are of primary importance because these often show the highest heat resistance as indicated by D_0 values of 4 – 5 min, with a few exceptional cases of D_0 >50 min recorded in the literature [40]. Both D and z values are affected by environmental conditions such as pH, food composition, or the presence of compounds with a "shielding" effect, e.g., fat. From the standpoint of food safety, the heat destruction characteristics of spores of the toxin-producing anaerobic bacteria *Clostridium botulinum* must be included in the process calculations, although their relatively low heat resistance (D_0 ca. 6 – 12 s) usually provides for a large margin of safety as compared to the heat-resistant thermophiles.

Table 8. Heat resistance parameters for microbial spores in food sterilization ∗

Microbial systems	D_0, min	z, °C
Thermophilic spore formers:		
Bacillus stearothermophilus	4 – 5	8 – 13
Desulfotomaculum nigrificans ∗∗	2 – 3	9 – 12
Clostridium thermosaccharolyticum	3 – 4	9 – 13
Bacillus coagulans	0.02 – 0.07	7 – 10
Bacillus subtilis	0.5 – 0.8	7 – 13
Mesophilic spore formers:		
Clostridium botulinum	0.15 – 0.3	8 – 12
Clostridium sporogenes	0.1 – 1.5	8 – 13
P.A. 3679	0.7 – 2.5	9 – 12

∗ Orientation data, generalized from various sources.
∗∗ Heat-resistant strains may show D_0 > 50 min in some types of foods.

The effectiveness of a process aimed at microbial destruction by heat is determined by the *total thermal death time value*, denoted as F_0 and calculated as a multiple of D_0 values for the most detrimental organisms in each specific case:

$$F_0 = n \cdot D_0$$

The constant n, sometimes referred to as the sterilizing value, is defined as the logarithmic span of the survivor curve for the initial and final numbers of the microorganisms c_0 and c, respectively, thus

$$n = \log\left(\frac{c_0}{c}\right)$$

Figure 17. Thermal destruction relationships in heat processing
A) Microbial survivor curves and corresponding D values at two different heating temperatures T_1 and T_2.
B) Thermal death time curves and corresponding z values for microorganisms and enzymes. ⟶Microorganisms; – – – Enzymes

Whereas the initial number of the microorganisms of concern (c_0) is usually estimated for each specific food, the real meaning of the final number c is the desired probability of survival of the organism. For *Clostridium botulinum*, the *12 D concept* is used in heat processing of all shelf-stable foods with pH $\geq$ 4.5; this means that if the initial population of *C. botulinum* spores is 1 spore per gram of food (not an unreasonable assumption based on experimental observations), a process satisfying the $F_0 = 12\,D_0$ requirement should result in $<10^{-10}$ probability of spore survival in a 100-g container, or, alternatively, in one surviving spore in 10^{10} of these containers. Because D_0= ca. 0.25 min for the most heat-resistant strain of this dangerous mesophilic pathogen, the minimum thermal death time required of all processes is $F_0 = 12 \cdot 0.25 = 3$ min. In actual industrial practice, the margin of safety for *C. botulinum* is usually much greater than 12 D because the processes are designed for destruction of much more heat-resistant thermophilic spore forming organisms with D_0 values of 4 – 5 min.

Because *C. botulinum* growth with toxin production does not occur at pH $\leq$4.5, *food acidity* is an important determinant of the sterilizing process conditions used. Low-acid products with pH >4.5 must be processed by the "pressure" cook method at a temperature >100 °C and must satisfy the 12 D concept for *C. botulinum*. High-acid foods (pH <4.5) need not be processed at elevated pressure; heating at atmospheric conditions, i.e., at 100 °C (the atmospheric cook) is usually sufficient to destroy spores of acid-tolerant spoilage organisms.

4.2.2. Process Calculations for Canned Foods

The typical F_0 values used by many processors correspond to a ca. five-to-sixfold reduction in D_0 for the most heat-resistant organisms. This minimizes any substantial quality changes in excessively heated canned foods while still achieving an acceptable rate of spoilage from nonsterile cans. For cans with a typical microbial load of ca. 1000 spores per can, the resulting spoilage rate is <1 per 1000 containers.

While the basic heat process design calculations are usually carried out for the theoretical F_0 values related to the reference temperature of 121 °C (250°F), the actual heating of the can content shows a time-dependent *heat penetration profile* (Fig. 18). The type of food product being processed, its thermal properties, and the can size and shape determine the heat penetration characteristics of the process. Because of the conduction heating mode, solid and semisolid foods (e.g., luncheon meats, gels, pastes, and purees) require a much longer heating time than liquid foods and liquids containing particulates (peas, corn, beans, etc. canned in liquid brines), which heat by convection. The experimentally determined heat penetration curve, with the TDT constants (D_0 and z) of the most deleterious organism of concern for the given food and the desired probability of spoilage are used to determine the required total lethal effect and, thus, the necessary time of heating.

Figure 18. Heat penetration curves
a) Convection heating (peas in brine); b) Conduction heating (luncheon meat)

The principle of the thermal process calculations can be illustrated by the straight-line formula describing the TDT curve (Fig. 17) for the heating times t_0 and t_e at the reference temperature θ_0 and any other experimental temperature θ_e, respectively:

$$\log \frac{t_e}{t_0} = -1/z\,(\theta_e - \theta_0) = \frac{\theta_0 - \theta_e}{z}$$

Using this formula for t_0= 1 min and θ_0= 121 °C, the lethal effect of any heating time t_e at temperature θ_e can be expressed in equivalent lethal time E_t defined as

$$\log E_t = \frac{\theta_0 - \theta_e}{z} \quad \text{or} \quad E_t = 10 \exp \frac{121 - \theta_e}{z}$$

The reciprocal values of the equivalent lethal times are referred to as lethality units L (thus,

$L = \frac{1}{E_t}$), indicating the lethality of heating for 1 min at a given temperature in terms of equivalent time required at 121 °C. For the customarily used $z = 10$ °C and common process temperatures θ (in °C), calculated values oflethality units L (in min equivalents at 121 °C) are as follows:

$\theta = 111$	$L = 0.100$	$\theta = 121$	$L = 1.000$
112	0.126	122	1.259
113	0.159	123	1.585
114	0.199	124	1.995
115	0.251	125	2.512
116	0.316	126	3.162
117	0.398	127	3.981
118	0.501	128	5.012
119	0.631	129	6.310
120	0.794	130	7.943

For more specific lethal tables including values other than $z = 10$ °C, see [41]. The total lethality of a given process can then be determined by integration of the lethality effects of the given heat penetration curve (shown in Fig. 18) for the total process time; thus,

$$F_0 = \int_{t_0=0}^{t} L\,dt$$

This is the basis for the *general method* developed by BIGELOW in 1920.

Determination of total process time to achieve a desired lethality (or the lethality evaluation of a given process time for each specific product or can size) involves considerable computational complexities, and several mathematical approaches, as described in specialized texts, have been developed to simplify the task [41], [42]. These include the improved general method, the formula method, the nomogram method, and various computer-based algorithms. In all cases, the data required for the process evaluation calculations include information about the type of microbial populations of the food being processed, the D_0 and z values of the most detrimental organism (i.e., the most heat-resistant or most populous contaminant or pathogen), the desired rate of survival/spoilage, the processing equipment temperature, and the heat penetration for the specific food and container being used. On the basis of the relative population numbers of the various microorganisms present and their D_0 and z values, the most detrimental organism against which the process is designed must be identified, and the final process lethality must be verified experimentally. Often the verification experiments include processing of packs inoculated with spores of an appropriate indicator organism such as the putrefactive anaerobe *Clostridium sporogenes*, which is similar to *C. botulinum* in terms of its thermal death time parameters. (One of its more heat-resistant strains used for the inoculation pack studies is often referred to as P.A. 3679.) Some orientation F_0 values of commercially processed canned foods are as follows:

Vegetables in brine	3 – 4
Baked beans	4 – 6
Fish products	5 – 8
Custards and puddings	4 – 10
Meat stews	12 – 15

The experimental determination of heat penetration data is carried out by inserting specially designed thermocouples in the coldest spot of an experimental can. The location of the cold spot depends on the heat transfer characteristics of the food being processed. From this standpoint, foods can be divided into three categories:

1) conduction heating foods, including mainly solid and pasty products, for which the coldest spot is usually in the geometrical center of the can
2) convection heating foods, typically liquids and liquids with small solid particles, for which the coldest spot is usually near the can bottom because of the convection currents generated in packs filled with these foods
3) intermediate or mixed heating mode systems, including liquids that may gelatinize on heating (starch-based foods, heat-sensitive protein foods such as egg white) or solids and highly viscous pastes that may liquefy at higher temperatures (high fat products, products stabilized with hydrocolloids), for which the position of the cold spot varies and changes as heating progresses.

Whereas the basic heating patterns are determined by the physical properties of the foods being heated, the heating rates are influenced by the heating medium used (steam, superheated water, or direct flame), and the particular process equipment used.

4.3. Food Canning Technology

Processing of foods in hermetically sealed metal cans is the most often used preservation tech-

nology for food sterilization by heating. In the broader sense, the term canning may be used to denote the general in-container sterilization principle for various other containers (glass jars, bottles, and plastic pouches) as well (→ Foods, 4. Food Packaging).

Figure 19. Diagrammatic representation of sanitary can components
A) Sanitary can architecture: a) Top seam (top lid); b) Side seam; c) Can body; d) Bottom seam (bottom lid) B) Detail of the double seam construction with the main measurement specifications: a) Cover lid; b) Can body; c) Sealing compound

The main steps involved in conventional canning operations are (1) the preparatory treatments (cutting, cleaning, pasteurization, blanching, ingredient mixing, etc.), (2) filling and sealing the containers, and (3) heating the hermetically sealed containers in conditions that prevent any contact of the food with the outside environment. The container seals must be strong enough to withstand the heating – cooling treatment with no mechanical damage that might allow for post-processing contamination. The typical cylindrical metal can used in conventional thermoprocessing of foods is specifically constructed for this purpose.

4.3.1. Sanitary Can Architecture

The metal containers used for traditional canned foods are referred to as "sanitary cans" (tins); this term denotes a three-piece container made from steel. Sometimes the steel sheet is plated with a thin layer of tin to inhibit the interaction of the food with the steel can material. Protective coatings commonly called "enamels" are also used for the same purpose. The basic aspects of sanitary can architecture are illustrated in Figure 19. Other types of cans may be used by the food industry for foods not subjected to the heat sterilization process (e.g., beer and pop cans, containers for pasteurized hams, or sweetened condensed milk cans); although these cans also fully satisfy the requirements of food hygiene and sanitation, they are not termed sanitary cans from the standpoint of construction.

The most important aspect of sanitary can architecture is the *double seam* (Fig. 19 B), which allows for attachment and hermetic sealing of the bottom lid (at the can producing factory) and the top lid (attached in the can sealing operation after filling with food). Routine periodic measurements of the double seams produced by the can filling – closing machinery must be carried out as one of the most important quality control procedures determining the safety of the finished product. Improperly formed seams can lead to mechanical defects created during heat sterilization processing and ultimately to nonsterility of the finished product.

Chances for oxidation reactions in the sterilized food in storage are minimized by the vacuum in the can created during filling. Several alternative evacuation procedures used by the industry include mechanical vacuum pumps and the "hot fill" and "steam exhaust" methods (in the last two methods the vacuum is created after cooling the container when the can content volume decreases or the steam in the head space of the can condenses). The creation of the vacuum eliminates reactive oxygen from the can. In addition, it also helps minimize potential seam

damage due to pressure buildup inside cans processed under higher than atmospheric pressure.

Figure 20. Principle of a still vertical retort
a) Retort lid; b) Retort body; c) Basket with cans; d) Safety vent

4.3.2. Conventional Retorting Equipment

The basic concept of the can sterilizing equipment is a pressurized vessel (retort) in which the cans are heated by saturated steam, superheated water under overpressure, or by steam – air mixtures [43]. After completion of the required heating process, the heating medium is replaced by cold water. The initial heating and cooling rates must be carefully controlled to avoid damage to the containers due to the pressure differences inside and outside the can.

The actual engineering design of the retorts varies widely in basic configuration; the vertical "still" retort (Fig. 20) is the simplest type of equipment used. Horizontal retorts that agitate the cans have been developed to increase the efficiency of heat transfer to the cans in the retort, whereas for increased capacity large "tunnel-like" horizontal designs can be used for whole pallet or crate loads of cans (Fig. 21). In general, conventional retorts are operated in a batch mode with the total required heating time determined according to the procedure outlined, and the heating – cooling cycle is carried out in the closed vessel in a predetermined processing sequence.

Figure 21. Horizontal retort with a crate carriage
a) Retort door; b) Crate carriage

Figure 22. The hydrostatic sterilizer principle

4.3.3. Hydrostatic Sterilizers

Continuous retorts have been developed and are becoming popular because they increase process efficiency, reduce labor costs, and improve the heat transfer rate by can agitation. In general, the preheating, heating, and cooling operations are carried out simultaneously in various parts of the equipment, with the cans travelling through the retort. In particular, continuous "hydrostatic cookers" (Fig. 22) have been successful industrially. The concept of the hydrostatic sterilizing tower is based on the use of steam as in a classical retort combined with the control of the proper

steam pressure needed for the processing temperature by preheating and cooling hydrostatic legs, placed before and after the steam sterilizing area. The cans are transported through the various sections of the tower by a conveyor belt, thus allowing for some agitation of the contents. Because of the height of the hydrostatic legs required, these sizeable installations are suitable for large throughputs.

Figure 23. Principle of the flame sterilization equipment
a) Heating conveyor; b) Holding conveyor; c) Cooling conveyor; d) Gas flame burners

4.3.4. Flame Sterilization

Direct heating of sealed cans over an open flame provides an effective thermoprocessing alternative, particularly for products packaged under high vacuum [44]. However, despite the potential advantages of the flame sterilization process, industrial use is not widespread and is presently limited mainly to canned mushrooms and some other acidified fruit and vegetable products. The *Steriflamme machinery design* (Fig. 23) consists of a set of conveyors carrying the cans with forward – backward rotational movement over rows of "heating" and "holding" natural gas burners followed by water spray cooling. An important aspect of flame sterilizers is the requirement for properly designed process control because the heating medium temperature may fluctuate, unlike in steam-based retorts. Various approaches to monitoring the adequacy of the heating process have been developed; one possibility is automatic surface-temperature measurement of each can by contact thermocouples at the beginning and the end of the temperature holding section. With a computerized data collection system, the F_0 of each can can be assessed against a predetermined necessary minimum F_0 value. The present state of this new thermoprocessing technology [44] appears to make it suitable mainly for specialized applications in small-output situations.

4.3.5. Retortable Pouches

As an alternative to the expensive and bulky steel can, thin-profile flexible containers made of plastic film (Foods, 4. Food Packaging) are rapidly gaining popularity in some countries. The principle of the retort pouch technology is the same as that of traditional canning: foods hermetically sealed in a plastic bag are subjected to a heating – cooling process adequate to achieve commercial sterility. However, because the pouch is constructed as a thin package, the heat transfer to the cold spot is much faster with less overheating of the outside food layers, in particular for convection heating products. The plastic films that are used must be sturdy enough to withstand the abuses of the handling and retorting treatments. For added mechanical protection and to minimize the oxygen and water vapor transmission through the plastic film in storage, the laminated packaging materials often include aluminum foil, and the finished pouch is marketed in a secondary paper box. The heat-sealability of plastic films is an advantage for easy seam formation. The main disadvantage of retort pouch technology appears to be the low capacity of the filling – sealing machinery due to the lightness of the package, resulting in higher labor requirements. The basic principle of pouch-pack technology was modified further for marketing a line of heat-sterilized complete entrees with an 18-month shelf life [45]. The dishes are vacuum packaged and sterilized in a patented, complex container consisting of a plastic tray sealed with a semirigid lid. The thickness of the complete Menu-Box container is ca. 40 mm, thus requiring a less damaging heat process similar to the standard pouch-pack.

Retortable pouches are usually heated by immersion in water with overpressure or in steam – air retorts. Both of these systems allow for proper maintenance and control of the external pressure at a level higher than that in the pouch. This is needed to protect the package from bursting because of internal vapor pressure buildup and to counteract expansion of the gases contained in the food. In the early stages of

pouch-pack technology development, the main concern was potential underprocessing of certain packages within the retort load due to a lack of homogeneity of heating environment and production of cold spots. However, the development of special retort racks for the pouches and the use of circulating and positive flow retorts have largely overcome these problems, as evidenced by the widespread use of retort pouch technology in Japan and other industrialized countries [43].

4.3.6. Aseptic Canning

Although built for the use of standard metal cans or composite cans made of different materials, the *James Dole aseptic canning system* differs from conventional canning. Rather than being heated inside sealed cans, foods are sterilized outside any package and the sterile food is then filled into presterilized cans. The filling and sealing of the cans is carried out under aseptic conditions provided usually by a steam-lock atmosphere or by dry, hot air. Thus, this system uses the same approach as Ultra-high-temperature processes (see Section 4.4.) for milk and other liquids and is, in fact, a special case of food sterilization technology known as aseptic processing.

4.4. Ultra-High-Temperature Aseptic Processing

Ultra-high-temperature (UHT) technology is widely used for processing milk and related dairy products, fruit juices, various beverages, and other mainly liquid foods. Although the term "UHT processing" in its strict meaning refers to the outside-the-package sterilization step only, it is commonly used to denote the technological sequence of two distinctly different basic unit operations: food sterilization and aseptic packaging. In addition, several auxiliary installations are often required in these continuous processing lines for specialized applications.

4.4.1. Theoretical Basis of UHT Processing

Typically, the *process temperatures* used in UHT sterilizing equipment are substantially higher than those for conventional retorting. In the dairy industry, temperatures of 135 – 150 °C are suitable for most of the products manufactured. At these very high temperatures, the desired thermal death time values (F_t) for the typical spore-forming spoilage microorganisms are on the order of several seconds, whereas the corresponding F_0 values would be on the order of several minutes. This is so because the microbial z values are generally small (Table 8), indicating a high sensitivity of microorganisms to temperature change. In contrast, the z values characterizing many undesirable chemical reactions caused by heat (vitamin destruction, nonenzymatic browning, and flavor changes) are larger (Table 9), resulting in a much flatter TDT curve. As illustrated in Figure 24, the use of ultra-high processing temperatures requires only a very short processing time, but still gives adequate lethality for microbial destruction while minimizing most of the deleterious chemical changes. Thus, the sensory qualities of UHT-processed products are usually higher than those of comparable in-container sterilized items. For this reason, the International Dairy Federation has defined UHT milk as a product distinctly different from both pasteurized and traditional "in-bottle" sterilized milk [40].

Table 9. Heat resistance parameters for chemical reactions in food sterilization ∗

Reaction	D_0, min	z, °C
Vitamin destruction	120 – 1200	25 – 45
Nonenzymatic browning (milk)	1 – 2	25 – 30
Color compound changes (chlorophyll and anthocyanins)	10 – 120	20 – 60
Enzyme deactivation	1 – 15	6 – 60
Denaturation of whey proteins (milk)		10 – 35

∗ Orientation data, generalized from [40] and other sources.

The *shelf life* of UHT-processed dairy products and other foods is not indefinite, as can be the case with properly processed canned foods. The main cause of spoilage is usually incomplete deactivation of some of the indigenous enzymes present. As seen in Table 9 and Figure 24, because of the higher z values for enzymes, the very short processing times do not achieve the same level of enzyme destruction as the much longer equivalent processing times required for sterilization at lower temperature. The slow but

noticeable residual enzymatic activity often limits the shelf life of UHT milk to ca. 6 months or less, depending on the type of heating equipment used.

The two main categories of UHT sterilizers are the direct or the indirect systems. The common features of all UHT heating processes are the very rapid heat-up and cool-down rates achievable with the liquids being processed. As a result, the total amount of heat imparted to the food can be controlled with great accuracy.

Figure 24. Optimum process conditions for UHT sterilization
a) Microbial spores destruction, 5 *D*; b) Vitamin destruction, 0.1 *D*; c) Enzyme deactivation, 1 *D*; d) Limit for browning

4.4.2. Ultra-High-Temperature Sterilization

The equipment used for continuous sterilization is designed to achieve the fastest possible heat transfer in the product. This is accomplished either by direct mixing of the heating medium, i.e., the culinary steam, with the food, or by heating a thin film of the food indirectly across a heat-transfer wall. The idealized time – temperature profiles of the two systems are illustrated in Figure 25.

The direct systems are capable of practically instantaneous heating because the condensing steam is mixed with the product providing a large amount of heat as the latent heat of condensation. The product being heated can be distributed as a thin free-falling film in a steam-filled chamber, as in the DASI system (Fig. 26), or the steam can be injected into the product in a special mixing head. In both cases the condensed steam must be subsequently evaporated to avoid product adulteration. Because heating an aqueous system to temperatures above 100 °C must be carried out under elevated pressure, the subsequent pressure drop caused by bringing the heated product to a vacuum chamber results in flash evaporation of some of the constituent water. Proper vacuum control insures that the amount of water evaporated equals that condensed in the product from the steam. As a result of evaporative cooling, the heat recovery into the incoming product is relatively poor in direct systems.

Figure 25. Idealized heating curves for direct and indirect UHT sterilizers [40]
– – – – indirect

The heating medium used in indirect UHT sterilizers is either superheated (pressurized) water or steam. The heat transfer into the product occurs across a heat-transfer wall of a pressurized plate heat exchanger or by a stainless steel pipe running through a steam chamber (Fig. 27). Although the heating rate is usually somewhat slower than in direct systems (Fig. 25), the possibility for heat regeneration from the heated product (Fig. 27) makes the indirect system more economical. However, product quality comparison for some dairy industry applications indicated less heat-damage-related changes in products obtained from direct systems [46]

4.4.3. Aseptic Packaging

The predominant aseptic packaging system used for the UHT-processed products is that developed by the Tetra-pak company *(Sweden)*.

The brick-shaped packagings are made of paper-based laminated material, which includes several layers of plastic film and aluminum foil (→ Foods, 4. Food Packaging). The packagings

Figure 26. Principle of the milk-into-steam direct heating system DASI
a) Preheater; b) Flash evaporation vacuum chamber

are formed from a continuous strip of the material, which enters the filling machinery through a hydrogen peroxide bath for package sterilization. Subsequently, the strip is formed into a tube around the sterilized product feed line, and appropriate longitudinal and cross seams are made by heat-sealing the plastic inner surfaces as the product is being filled. This continuous aseptic packaging system is unique in that it does not require an aseptic chamber, as in the case of some competing systems like the preformed carton-based Combibloc, the various form-fill-seal or preformed cup systems [47], or the James Dole aseptic canning (see Section 4.3.6). Because the filling machinery may experience more frequent interruptions as compared to UHT sterilizers, aseptic processing systems customarily include an aseptic storage tank for the sterilized product before the filler.

Although UHT aseptic processing is predominantly used with liquid foods, systems allowing for handling liquids with particulates are also available. Some of these seldom used or experimental systems have been reviewed [44]. The technological approaches include separate heating of the liquids and the particles in a regular UHT machine and in a batch reactor, respectively, followed by aseptic mixing and packaging, or a scraped surface heating of the liquid – solid mixture with positive displacement feed pumps controlling the required pressures. Heating of particulates in a liquid food material that forms a part of the final product (e.g., meat in a sauce or vegetables in a soup) may result in substantial overheating of the liquid phase, contributing to possible quality defects [40].

a) Sterilizing chamber; b) Regenerative heater–cooler

4.4.4. Quality of UHT-Processed Foods

Although UHT-sterilized products are shelf-stable and need not be refrigerated, their shelf life may be limited due to the *slow deteriorative chemical reactions.* In the case of milk and other dairy products, residual proteolytic activity may cause product gellation or sweet curdling [40], whereas incompletely inactivated lipases (especially the more heat resistant ones of microbial origin) cause hydrolytic fat breakdown, resulting in rancidity after prolonged storage. Because whey protein denaturation, which is the chemical reaction responsible for cooked flavor development in dairy products, has a relatively steep TDT curve (Table 9) with z values similar

to those for microorganisms, the cooked flavor development in UHT-sterilized milk cannot be fully eliminated by any time – temperature combinations. Direct heating systems appear to produce less cooked flavor because of better control of the heating process as well as subsequent vacuum treatment of the heatedmilk. The strong cooked flavor in freshly processed UHT milk diminishes after ca. 10 – 12 d storage.

The *nutritional quality* of UHT-processed foods, such as milk, is comparable to that of a fresh rather than a canned product [48]. The destruction of heat-labile vitamins by the UHT sterilization process is minimal, particularly in direct systems. However, some loss may occur during subsequent prolonged storage, especially because the plastic-to-plastic seams of the paper-based containers do not give absolute protection against oxygen penetration.

Nonsterility of UHT products may result from insufficient heat treatment, often related to presence of unexpected heat-resistant organisms, or because of postprocessing contamination particularly in the aseptic storage or the aseptic filling operation. The vacuum treatment of the sterilized product in direct systems increases the potential for postprocessing contamination in these machines compared to indirect processes. Any mechanical fault in the vacuum chamber, which allows entry of outside air, can cause major problems as in the case of imperfect seams in cans. The typical rate of spoilage in successful industrial UHT systems ($<0.1\,\%$) is comparable to the spoilage rate of conventionally processed canned foods.

4.5. Spoilage in Heat-Sterilized Foods

The shelf life of canned or UHT-processed foods depends on deactivation of all microorganisms capable of growing in the foods rather than on altering the environmental conditions necessary for microbial growth. Thus, any presence of viable microorganisms in a processed product stored without refrigeration may result in product spoilage, or even, in the case of surviving pathogens, in an outbreak of food-borne illness.

Two main reasons for microbial growth in sterile products are insufficient sterilization (underprocessing) or postprocessing contamination. *Underprocessing* may be caused by poor time – temperature control of an otherwise properly designed process, by the unexpected presence of highly heat-resistant strains [40], or by unusually high loads of microbial contaminants. Underprocessing often results in initial survival of small numbers of a specific organism giving rise to single-culture growth. This can be particularly dangerous in the case of toxin-producing pathogens growing without the competition of other spoilage organisms. Some of the typical spoilage bacteria found in underprocessed cans are homofermentative thermophilic spore formers, producing only acids as a byproduct of their growth; the resulting type of spoilage is termed "flat-sour," as no visible bulging of the can ends occurs. When the surviving organisms are heterofermentative, producing CO_2 gas in addition to the acid, the spoilage is easily recognized by the swollen package appearance. Organisms producing H_2S during their growth give rise to the "sulfur stinker" type of spoilage. Examples and characteristics of various spoilage types are as follows:

Flat-sour:	acid spoilage, no gas
Flipper, springer hard swell:	can swollen due to CO_2 gas produced
Sulfur stinker:	H_2S gas produced, darkening of can content
Postprocess contamination:	mixed microflora
Hydrogen swell:	chemical reaction of food with can material, H_2 gas only, no microbial spoilage

In contrast to underprocessing, *postprocessing contamination* typically produces a mixed population growth pattern. In the case of canned products, postprocessing contamination occurs because of imperfections in can seams, which allow entry of bacteria either during the cooling cycle in the retort resulting in creation of a vacuum in the can, or during storage. In aseptically processed foods, postprocessing contamination may be caused by failure of the various aseptic systems, needed for the food handling downstream from the sterilizer, as well as by faulty package seams.

Occasionally, *container swelling* may be experienced with heat-processed sterile foods without any signs of microbial growth. In canned products, this may be caused by the chemical reaction of an acid food with the metal of the container where the protective enamel or tin layers may have microscopic imperfections. If the resulting gas is exclusively hydrogen, the defect is

termed "hydrogen swell." Sterile foods in paper-based containers or in plastic retort pouches may show weak signs of swelling caused by gases liberated by reactions of incompletely deactivated enzymes. Incomplete degassing of products during filling before pouch-pack processing can also be a cause of package swelling. Despite the harmless nature of these "chemical swells," the potential health hazards involved in ingesting any sterilized food showing signs of spoilage should be considered when swollen shelf-stable food containers are handled.

To minimize spoilage problems at the retail level, canned foods as well as UHT-processed products are usually held in processors' warehouses for several weeks. During this time, randomly selected containers are subjected to quality control tests involving incubation at various temperatures and microbiological analyses. If a potential spoilage or a food-borne illness problem is discovered after the release of the product batch to commercial networks, elaborate and costly recalls may be necessary. However, despite a worldwide annual production of shelf-stable food containers in large amounts, the safety record of this important segment of the food industry is outstanding.

5. Food Preservation by Ionizing Radiation

5.1. Radurization, Radappertization, and Radicidation

The use of radiation energy for food preservation has been the subject of ongoing research since 1945. Much of the basic scientific information has been amassed at several centers around the world, including the U.S. Army Research Center at Natick, Mass.; Michigan State University; the Bundesforschungsanstalt für Ernährung (Federal Research Center for Nutrition), Karlsruhe, FRG; and similar centers in Holland, the former states of USSR, Israel, and other countries. Because irradiation can destroy microorganisms without any damaging effects on the main food nutrients or food quality attributes of many foods, early research has been focused on development of irradiation technology to replace heat sterilization. Other promising applications of irradiation included shelf-life extension of vegetables due to sprouting inhibition, or increased food safety by elimination of potential pathogens such as *Salmonella*. However, despite the main advantage of the process in terms of final product quality, the experimentally confirmed safety of irradiated food and changes in the regulatory position of many countries, which now consider irradiation a process (rather than a chemical additive, as in the past), food irradiation is a controversial issue and is not likely to gain widespread public acceptance for some time.

Figure 28. Relative lethality scale for ionizing radiations

The principle of food preservation by irradiation is the same as in heating: however, radiation energy (rather than heat energy) is used to deactivate microbial contaminants, resulting in elimination of microbial growth. When a low amount of radiation energy is used, elimination of only selected, radiation-sensitive organisms results in prolonged shelf life, but the product is not shelf stable; because this is the same as in pasteurization, the term *radurization* has been proposed for this use. For complete food sterilization by irradiation, the proposed term is *radappertization* (in honor of the inventor of the canning process, Frenchman Nicolas Appert, 1752 – 1841); however, the radiation energy requirement for this treatment exceeds permissible doses. Radiation energy can also be used for deinfestation of foods subject to insect contamination (tropical fruits, herbs, spices, grains, etc); the term *radicidation* is sometimes used to describe this treatment. Other food-related uses of irradiation have been proposed or approved in many countries; these include the inhibition of sprouting in stored vegetables (potatoes, onions, and garlic); the treatment of food processing wastes and other wastewaters for microbiologically safe disposal; low-dose irradiation for delayed ripening of fruits; sterilization of complete meals for hospital patients experiencing adverse

immunoreactions or requiring an aseptic environment; and sterilization of food packaging materials. A similar use for sterilization of laboratory and medical disposables is currently the largest industrial application of the bactericidal effects of irradiation.

5.2. Theoretical Aspects of Food Irradiation

When foods are irradiated to prolong their shelf life, the process is aimed primarily at *destruction of microbial viability*, similar to heat processing. The lethal effects of ionizing radiations are well-known since the times of W. K. Röntgen (1845 – 1923), Henri Becquerel (1851 – 1908), and the nuclear attack on Hiroshima (Japan). In general, the more complex the biological system, the lower energy dose is needed for a lethal effect. Deactivation of microorganisms requires much higher energy doses than insect deinfestation or sprouting inhibition (Fig. 28). Simpler chemical systems, such as single protein or enzyme molecules, are not greatly affected by the radiation energy.

The lethal effect of irradiation can be expressed in the same way as the effects of heat; whereas in heat-induced deactivation reactions, both time and temperature were important (see Section 4.2.1) as determinants of total energy dose, the irradiation dose is simply defined as the amount of radiation energy absorbed by the mass. The SI-unit of radiation dose is 1 gray (Gy), defined as the radiation energy of 1 J absorbed by 1 kg of mass; thus, 1 Gy = 1 J/kg. An older unit still widely in existence in the literature is 1 Rad (also rad or rd) and its multiples kRad (= 10^3 Rad) or MRad (10^6 Rad); the relationship between Gy and Rad is 100 Rad = 1 Gy. Although the radiation dose effect may be influenced by the rate of exposure or "dose rate" (the amount of energy absorbed per unit time), food-related irradiation effects can be accounted for by the total dose only.

The recommended *maximum dose* for food irradiation approved by the Joint Expert Committee on Food Irradiation of the United Nations (with internationally recognized authorities representing the FAO, the WHO, and the International Atomic Energy Commission) is 10 kGy. Practical doses considered adequate for specialized food application are ca. 0.02 – 0.15 kGy for sprouting inhibition, 0.15 – 0.3 kGy for insect deinfestation of fruits or for parasite control in meats (such as trichinosis in pork), and 1.0 – 2.0 kGy for radurization of meat, poultry, and seafood [49].

In a manner analogous to heat deactivation of microorganisms, a *decimal reduction dose* (DRD) has been determined for various types of organisms as the amount of radiation energy needed to deactivate 90 % (1 log cycle) of the populations present. Some orientation DRD values (in kGy) for several types of microorganisms are as follows:

Spores	
Clostridium botulinum	3.3 – 3.7
P.A. 3679	2.2
Vegetative cells	
Salmonella typhimurium	0.2 – 0.8
Staphylococcus aureus	0.1
Yeasts and molds	0.4 – 0.5

As can be seen, *Clostridium botulinum* is one of the most radiation-resistant organisms; this alone is a serious obstacle to development of shelf-stable irradiated foods for general use in the retail market.

The exact *mode of action* of the irradiation energy with respect to its lethal effects is not well understood. Possible alternatives include "direct hit" of the biological cell nucleus by the high-energy particles, or indirect chemical effects of the radiation energy on proteins, carbohydrates, or lipids, resulting in formation of highly reactive free radicals. These molecules, formed, e.g., by splitting a hydrogen atom from a hydrocarbon chain, can cause chemical changes within the living organisms. Similar chemical reactions also occur in the food components themselves, giving rise to various "radiolytic off-flavors" noticeable especially in foods irradiated at higher doses.

The *industrially applicable types of ionizing radiations* are β-rays or γ-rays. However, for practical food applications, β-rays (a stream of electrons generated by an electron accelerator) are less suitable than γ-rays (electromagnetic radiation of very short wavelength) because of the high cost of the equipment and the low penetrability of the β-rays energy. The γ-ray sources used commercially are predominantly the radioactive elements ^{60}Co or ^{127}Ce. The penetra-

tion depth of γ-rays (30 – 50 cm as compared to ca. 5 cm for β-rays) is a major advantage for irradiation processing of foods, as conceptual equipment designs can be based on processing of whole crate or pallet loads of products in commercial packages.

5.3. Food Irradiation Technology

The potential for food irradiation as a food preservation technology is hampered not only by unfavorable public image (common to any process based on radioactivity), but also by the high installation cost of the γ-irradiation equipment. Because of the need for highly sophisticated safeguards in handling the radioactive elements, the high throughputs achievable with even low emitting sources are of little consequence in reducing cost.

Typical plant installation proposals illustrate the basic common principle of a conveyorized product passage through a heavily shielded irradiation room [1], [50]. The bank of radiating rods is held submerged in a pool of heavy water, and a combination of safety switches and other precautionary measures prevent the constantly emitting source from being engaged in the working position before the food product is introduced. Various single- or multiple-pass designs can be considered, depending on the size of the packages to be irradiated, the limiting exposure dose to prevent any undesirable radiolytic product changes, and other technical factors [50].

Specialized equipment installations for individual food processors appear uneconomical at the present time. Where a whole segment of a given industry can be served in one location, cost-sharing may prove feasible. For example, deinfestation irradiation of papaya fruit shipped from Hawaii to the continental United States has been considered as a viable industrial option to prevent epidemic outbreaks of adult fruit flies [50]; in Canada, irradiation of fish for prolonged shelf life, allowing wide market distribution without freezing, has been studied in a pilot-plant project. In Japan, an irradiator for treatment of potatoes to prevent sprouting has been installed with a capacity of 15 000 t/month. In some cases, existing irradiator installations serving other than food industries could be used in co-processing agreements for selected food applications. Examples of industrial uses of food irradiation technology are listed in Table 10.

Table 10. Examples of industrial uses of food irradiation

Product	Reasons for irradiation	Dose, kGy
Potatoes, onions, and garlic	sprouting inhibition	0.02 – 0.15
Bananas, avocado, mango, papaya, and other tropical fruits	delayed ripening	0.2 – 0.4
Papaya, mango, peaches, other fresh or dried fruits, grain, and flour	insect deinfestation	0.15 – 0.75
Mushrooms, strawberries, asparagus, and endive	prolonged storage, delay of spoilage	1.0 – 2.5
Poultry, fish, seafood, pork, and beef	*Salmonella* control, prolonged shelf life	0.5 – 6.0
Pork	control of trichinosis	0.15 – 0.30
Herbs and spices	reduction of microbial contamination	1.0 – 2.0
Special hospital meals	sterilization for patients with specific needs	$\geq$25

Potential advantages of radiation-processed foods are prolonged shelf life without any deleterious sensory effects, greater retention of heat-sensitive nutrients (since the processing is carried out at low temperature), and increased safety of foods potentially associated with pathogens (such as poultry products, mussels, or other seafoods). Various foods have different sensitivities to radiolytic quality changes; some foods (e.g., herbs) can be irradiated at relatively high dose without any noticeable flavor defects, whereas dairy foods appear quite sensitive even to low-dose irradiation [51]. In general, the irradiation-related flavor and texture changes developed in foods are not completely understood, although animal as well as volunteer human feeding tests with even high-dose irradiated products did not indicate any toxic or other deleterious health effects. For certain experimental applications (e.g., radappertization of meat products) irradiation in the frozen state eliminates any undesirable flavor development and still achieves the desired lethal effect on the microorganisms. However, because irradiation is not effective for enzyme destruction, a mild heating step is often required as a radappertization pretreatment, not unlike blanching of vegetables before sterilization by canning.

Although the food irradiation process has been subjected to research and testing scrutiny unprecedented in the history of food technology, prospects for its widespread use are not bright,

especially with the current post-Chernobyl apprehensions. However, specialized applications will undoubtedly increase, including even the possibility for occasional undeclared low-dose treatments of international raw material shipments to decrease microbial contamination. Currently, no effective chemical tests are available to analyze foods for possible low-dose irradiation treatments as no detectable chemical changes occur.

6. Other Food Preservation Methods

Shelf-life extension of processed foods may be accomplished by several other means in addition to the principal technologies discussed in Chapters 2, 3, 4, 5. Refrigerated storage of fresh or processed food items is perhaps the most universal method used to retard food spoilage. Any process involving heat (pasteurization, blanching, cooking, baking, or frying) produces foods that can be kept for an extended time at proper storage conditions (temperature and packaging). Processes such as fermentation, pickling, smoking, and salting or sugaring of fish, sausage, dairy products, vegetables, fruits, etc. are used for preservation, as well as for diversification of the market selection. All these processes offer limited extension of shelf life by altering the environmental conditions conducive to microbial growth, as summarized in Table 11. Often several aspects of these techniques are combined in the processing – storage conditions applied (e.g., refrigerated storage of yogurt, highly acidic environment for packaging fermented fish, etc,). In many processed foods today, chemical preservatives are used as one of the complementary methods contributing to extension of shelf life.

6.1. Chemical Preservatives

Many naturally occurring components of food have antimicrobial properties. For example, cranberries contain ca. 5 % benzoic acid, which is commonly added as a preservative to jams and similar products. Propionic acid and its salts (calcium or sodium propionates) are effective antimold compounds added to bread, but produced naturally in Swiss cheese. Some lactic acid bacteria used in fermented dairy or meat products appear to produce metabolites with weak antibiotic properties. In many countries, selected antibiotics are allowed as food preservatives, particularly when applied to the surface of packaged foods such as cheese and fish.

The effectiveness of chemical preservatives is usually limited, especially in the low concentrations that are approved for various applications. However, their use enhances the effect of other food preservation methods such as refrigeration, packaging, or modified atmosphere storage. As one class of the large group of food additives, chemical preservatives are subject to stringent regulations (→ Foods, 3. Additives, Chap. 3.1.).

Table 11. Food preservation principles of various food processing operations

Process	Product example	Preservation principle
Fermentation	dairy products, some sausages, herring, and other fish	lowering of pH below tolerance limits of many microorganisms
Pickling	vegetables, fish, and mushrooms	pH control or increased salt content inhibits microbial growth
Smoking	meat products, cheese, and fish	some bacteriostatic effect of smoke; drying of the surface layers; sometimes heat effects
Salting	fish, mushrooms, and meat	lowering of a_w below microbial tolerance limits
Sugaring	candied fruits, jams, and jellies	lowering of a_w as in salting

6.2. Modified Atmosphere Packaging

The use of a modified gaseous environment to retard spoilage of fresh foods has emerged in the 1930 s mainly for transoceanic shipments of fresh meat to the United Kingdom. Later, development of controlled atmosphere storage systems to eliminate spoilage due to respiration of freshly harvested fruits extended the availability of certain seasonal produce (apples and pears) to many months. Inert gas (principally N_2) has been used for a long time in packaging of dried foods, such as whole milk or instant coffee, to prevent oxidative reactions during prolonged storage. The principles of these modified atmosphere storage techniques are well understood [52–54]. However, extension of the shelf life of perishable foods by modifying the atmosphere inside the retail containers (with or without concomitant use of refrigeration) is a relatively new concept that is still in the development stage [55–58].

Carbon Dioxide. The principal aspect of modified atmosphere packaging is the use of CO_2 as the primary component of the gaseous package atmosphere. The CO_2 gas acts as an inhibitor of microbial growth for many spoilage organisms, especially some of the psychrotrophs capable of growth at refrigerated temperatures, as well as many molds. Other bacteria, such as the lactic acid producing organisms, are not greatly inhibited by CO_2. Most of the food-related pathogens, including *Salmonella* species, *Staphylococcus aureus*, and *Yersinia enterocolitica*, do not multiply in a high CO_2 atmosphere; however some anaerobic pathogens, including *Clostridia*, are capable of growth with the CO_2 present. So far, modified atmosphere packaging appears suitable for shelf life extension of refrigerated products including meat, fish, and poultry, but it cannot be used as a substitute for refrigeration in foods where growth of the toxin-producing *Clostridium botulinum* can occur. For certain foods, especially bakery products, modified atmosphere packaging without refrigeration has been successful in industrial applications for shelf life extension to several weeks [59].

The exact mode of action of CO_2 in retarding microbial growth is not well understood. However, packaging atmospheres with up to 60 – 75 % CO_2 (with the balance consisting of O_2 and N_2 in varying proportions) have been used successfully to retard spoilage of many fruits, vegetables, meats, and other products. Because high CO_2 content in fresh meat packages can result in discoloration of the red meat pigment, incorporation of CO has been proposed (but not approved) as an experimental solution.

As a predecessor to controlled atmosphere packaging, the *vacuum packaging* of fresh or processed foods in gas-impermeable plastic containers has been used since the late 1950 s. This practice, in fact, establishes an atmosphere with up to 30 % CO_2 within the package because of metabolic and respiratory processes [56]. Fresh produce, such as cut-up green salads, packaged for institutional use in gas-impermeable plastic bags, creates its own modified atmosphere conditions by using the O_2 from the air in the package and producing CO_2 as a result of respiration [58].

7. Nutrient Retention in Processed Foods

The main objective of long-term food preservation is to extend the availability of seasonal food materials and thus, to maximize the use of their component nutrients. Apart from water, which is the most abundant component of most fresh food materials, the principal nutrients found in all foods are carbohydrates, proteins, and lipids. With the water, these macronutrients often account for more than 95 – 99 % of the food content. The remainder of the food components are the micronutrients, including minerals, vitamins, indigestible fiber ("bulk"), and other minor components such as organic acids, dissolved gases, etc.

The processing and storage techniques used to extend food shelf life affect the individual nutrients to a varying degree. Nutritional properties of the macronutrients, including the food energy values of the proteins and carbohydrates (16.5 kJ/g) and lipids (37 kJ/g) are not greatly affected by any of the long-term preservation techniques. The chemical reactions imparted by exposure to heat in drying or canning may cause denaturation or alter functionality of certain proteins (solubility, coagulation, and emulsifying properties), but this alone does not affect their nutritive value. However, exposure of systems containing both proteins and reducing sugars to severe heating may induce the nonenzymatic (Maillard) browning reaction, during which some of the essential amino acids from the proteins (principally lysine) become less available as nutrients for human body metabolism [60]. Similarly, oxidative reactions in lipids may result from processing (e.g., by irradiation) or prolonged storage without exclusion of oxygen (especially dried or frozen foods). These changes may lead to sensory defects in the products (e.g. rancidity or bitterness) but not necessarily to losses of nutritive value. Physical losses of these macronutrients may sometimes occur as an indirect result of the long-term preservation processes (e.g., loss of the water-soluble sarcoplasmic meat protein in the drip loss after thawing of frozen meats) or because of the various preparatory treatments needed for optimum quality retention (e.g., loss of water-soluble carbohydrates in water blanch-

ing of fruits and vegetables prior to drying, freezing, or canning). The same physical losses may also occur with water-soluble micronutrients, especially the minerals and vitamins, whereas fat-soluble vitamins are removed in preprocessing operations like skimming of milk before drying.

The main concern over nutrient losses in long-term food preservation usually concerns the *vitamins*, many of which are sensitive to heat, light, oxygen, and other factors encountered in the processing and storage conditions that are required. Continually expanding knowledge of the specific properties of the individual nutrients allows process technology improvements targeted specifically for maximization of nutrient retention. Technological advances (such as the UHT processing or food irradiation) also contribute to industrially realistic process modifications leading to less nutrient destruction. However, vitamin losses occur in prolonged food storage even under the best achievable conditions. In general, processing and storage effects on micronutrients in dried, frozen, or canned food must be expected as the trade-off for availability of macronutrients well beyond the growing season or the limited shelf life of fresh food materials.

1. Introduction

Food additives are substances that are intentionally added to food, without themselves being considered food in the ordinary sense of the term. The term "food additive" is defined differently by the food laws of individual countries. As examples, the definitions used in the Codex Alimentarius, in the United States, in Japan, and in the Federal Republic of Germany are given in Chapter 6. Food additives are indispensable for the production and processing of many foods. Some are essential for the economic production and distribution of foods. Together with contin-

10.1002/14356007.a11_561

ued improvements in food technology, additives ensure the general availability of high-quality food with a satisfactory shelf life. The four basic reasons for using additives are

1) to influence the nutritive value of food,
2) to improve the stability of food,
3) to affect the sensory properties of food, and
4) to make certain technological processes possible.

Food additives are sometimes used to produce food more cheaply. However, they may not be used to deceive the consumer, for example, about the character or freshness of food. Furthermore, additives must not adversely affect food quality.

The properties and production methods of some additives are described in other articles; the reader is advised to consult the cumulative index for specific products. The following discussion is, therefore, confined to more general and universal aspects.

1.1. History

Two preservatives, smoke and salt, are probably the oldest food additives. They were also used to give food a good taste. Like spices, they have been used since prehistoric times to improve the taste of food from plant or animal sources. These foods were either eaten raw or prepared over an open fire. Until the 18th century, the use of additives remained low. However, with the beginning of industrialization in the 19th century, an increasing number of people moved to towns. This meant that they had less time available to provide and process their food. More and more food was produced either by specific craftsmen or industrially. Additives became increasingly necessary; especially those that protected food against spoilage. Some food additives introduced in the 19th century are still being used today, e.g., baking powder, benzoic acid, and saccharin. However, others in use at that time do not comply with current toxicological requirements and have thus disappeared from food processing.

In the 20th century, the industrial production of food developed further and the importance of additives increased. Thus, the invention of processed cheese (→ Cheese, Processed Cheese, and Whey, Chap. 6.) in 1913 would have been impossible without the development of emulsifying salts, such as citrates, phosphates, or similar substances. During this time emulsifiers were developed which improved and simplified the production of margarine. Additives used in certain food for physiological reasons have also become important, e.g., trace elements, vitamins, and essential amino acids. More recently, the importance of aroma and flavor enhancers, as well as flavoring compounds, has increased substantially.

Hygienic and legal controls have also been tightened considerably in this century. One example of this is in coloring agents. Many substances used in the first half of the 20th century have not survived modern toxicological requirements.

Despite all the advances, unresolved problems still remain in the area of food additives, e.g., finding substitutes for two specific types of preservative, nitrite and sulfite, which are considered undesirable for various reasons. The search also continues for substances or processes that can be used to reduce the undesirably high levels of sugar and common salt in some foods, without impairing their quality. The financial risks involved in developing new food additives are high because development of a new food additive is now almost as expensive as developing a new drug. Even when additives have been evaluated successfully and necessary authorization under food law has been obtained, the cost of development can be recovered only if the additive can be used widely.

1.2. Safety Aspects

Some people still harbor an aversion to food additives. This can be explained by earlier, uncontrolled use of chemicals in food processing. Today, food additives are authorized only if no harmful effects of any kind can be shown after extensive toxicological testing. Many additives have undergone more rigorous testing than some foods or food components.

To date, no internationally binding standards exist for the toxicological testing of additives. The most widely accepted guidelines are those laid down by expert committees of the WHO

[1]. The U.S. regulations [2] are also observed widely.

Additives are tested for their acute, subchronic, and chronic toxicity, as well as for carcinogenicity, mutagenicity, teratogenicity, and biochemical behavior. Before testing begins, the substance must be chemically and physically homogeneous and pure. As a matter of principle, a food additive should not be pharmacologically active at the concentration at which it is used. For obvious reasons, the testing of additives is carried out largely on animals. The tendency away from animal testing is increasing, but at present, this is only possible in a few areas.

Acute toxicity, expressed as LD_{50}, and subchronic toxicity, established by the so-called 90-day test, are only crude measures of the toxicological properties of a substance. The acute toxicity of food additives should always be as low as possible to prevent poisoning even in the case of accidental overdosing or misuse.

Chronic toxicity is more important. The specifications for food additives are far more strict in this respect than those for drugs, because additives may be consumed continuously for a very long period of time. Also, in contrast to drugs, side effects are not considered an acceptable risk with food additives.

Food additives must not be mutagenic or teratogenic. Because they are absorbed exclusively via the gastrointestinal tract, carcinogenicity is tested mainly by feeding.

Biochemical tests are performed to determine the extent to which a food additive is absorbed by the organism, the factors affecting its absorption, its distribution within the body, and the manner in which it is excreted. Four basic possibilities exist:

1) A substance is excreted quickly and unchanged. Examples of this are the sweeteners saccharin [*128-44-9*] and acesulfame-K [*55589-62-3*].
2) A substance is quickly metabolized within the body and excreted in this metabolized form. An example is the preservative benzoic acid [*65-85-0*], which is converted in the body to hippuric acid [*495-69-2*], by reaction with glycine [*56-40-6*], and excreted in this form.
3) A substance is utilized quickly as a nutrient. Some examples are the preservative sorbic acid [*110-44-1*] and the sweetener aspartame [*22839-47-0*].
4) A substance is excreted more slowly than it is absorbed and thus accumulates in the body. An example of this is boric acid, used as a preservative in the past. Such substances are considered undesirable and are no longer used as food additives.

Table 1. Acceptable daily intake (ADI) values of some food additives

Additive	CAS registry no.	ADI, mg/kg per day
Acesulfame-K	[*55589-62-3*]	0 – 9
Alginates		0 – 50
Amaranth	[*915-67-3*]	0 – 0.75 (temporary)
Ascorbic acid	[*50-81-7*]	0 – 15
Aspartame	[*22839-47-0*]	0 – 40
Azo Rubine	[*3567-69-9*]	0 – 4
Benzoic acid	[*65-85-0*]	0 – 5
Butylated hydroxyanisole	[*25013-16-5*]	0 – 0.5
Butylated hydroxytoluene	[*128-37-0*]	0 – 0.5
Caramel (ammonia process)		0 – 100 (temporary)
Cellulose ethers		0 – 25
Cyclamate	[*100-88-9*]	0 – 11
Erythrosine	[*16423-68-0*]	0 – 2.5
Ethyl maltol	[*4940-11-8*]	0 – 2
Fumaric acid	[*110-17-8*]	0 – 6
Gallates		0 – 0.2
Nitrates		0 – 5
Nitrites		0 – 0.2 (temporary)
Phosphates		0 – 70
Quinoline Yellow	[*8004-92-0*]	0 – 0.5 (temporary)
Saccharin	[*128-44-9*]	0 – 2.5 (temporary)
Sorbic acid	[*110-44-1*]	0 – 25

Animal trials are conducted to determine the concentration to which an additive remains nontoxic. Expert WHO committees use this value to define the *acceptable daily intake* (ADI) by reducing it by a factor of 100 (except in special cases). This takes into consideration the following facts: the food intake of some animals, relative to their body weight, is greater than that of humans; that some people (e.g., children, the sick, and the elderly) show special metabolism; and the ADI applies over the entire life-span.

The ADI is related to kilograms of body weight and is the amount of additive in milligrams that can be consumed safely per day (this

includes the reduction by a factor of 100). The ADI values of some food additives are given in Table 1. The actual consumption of food additives is generally far lower than the ADI. For preservatives in the Federal Republic of Germany, consumption is about 1 – 10 % of the ADI. Only sulfur dioxide is consumed in larger amounts [3].

2. Substances with Nutritive and Other Dietary Effects

The human organism requires regular supplies of about 40 – 50 nutrients if all bodily functions are to proceed smoothly. If even one of them is missing or present in insufficient amounts, deficiency symptoms result. A particularly well-known example of this is scurvy, i.e., vitamin C deficiency.

All nutrients and nutritive supplements needed by the body are normally present in sufficient amounts in food. However, in exceptional cases or with unbalanced diets, the amount of these substances may be insufficient. Some can be destroyed or lost during processing or storage. In such cases, these nutrients can be added in a controlled manner.

Substances with nutritive and dietetic functions are added to food to increase its nutritive quality or, in special cases, to reduce it in a controlled way. Some of these substances may also ameliorate metabolic disorders with a dietary or physiological cause and correct various deficiencies.

Incorporating these substances homogeneously is sometimes difficult because they must be added at very low concentrations to relatively large quantities of food. In such cases, special premixes are used to allow easier incorporation into the appropriate food. Some substances with nutritive and dietary effects are particularly susceptible to degradation, especially by oxidation. Therefore, they must be stabilized. In practice, this is achieved by the synthesis of especially stable molecules which will remain physiologically and dietetically effective, by the use of stabilizing additives, or by encapsulation with suitable carrier materials (e.g., microencapsulation).

2.1. Vitamins and Provitamins

(→ Vitamins)

Vitamins are used as food additives for dietary reasons, when sufficient vitamins are not supplied by the food itself or when losses have occurred during processing. Natural variation in the vitamin content of food can also be adjusted in this way. Vitamins may also be added when the body is unable to absorb sufficient amounts of the vitamins contained in food [4–6]. The controlled addition of vitamins to food is called *vitaminization,* and the addition to compensate for processing losses is *revitaminization. Enrichment* or *fortification* means the addition of vitamins beyond the natural content.

Standardization means adjustment of natural variations. Oversupply is harmful only with the fat-soluble vitamins A and D, because it can lead to so-called hypervitaminoses.

Examples of *revitaminization* are the addition of vitamins A and D to skimmed milk and the addition of B vitamins to cereal. Examples of *standardization* or *enrichment* are the addition of vitamin C to beverages or fruit products and the addition of vitamin D to milk. Vitamins are added to some foods that naturally contain few or no vitamins because they constitute a particularly suitable carrier for a particular vitamin. An example of this is the addition of fat-soluble vitamins A and D to margarine (→ Margarine and Shortenings).

Vitamins and provitamins can also be added to foods for technological reasons. For example, ascorbic acid [*50-81-7*] and tocopherols have an antioxidative effect (see Section 3.2), and some carotenoids with vitamin functions are important food colorants (see Section 4.1).

2.2. Amino Acids (→ Amino Acids)

Some amino acids are added to foods for technological reasons, e.g., flavoring or flavor enhancers (Chap. 4) or baking aids (Section 5.11). Their use as food additives for *dietetic reasons* is restricted to the essential amino acids, i.e., those which the body cannot synthesize. These are added to food for the same reason as vitamins. During food processing, lysine [*56-87-1*], in particular, can react with carbohydrates by the Maillard reaction to form compounds from which it

is no longer physiologically available. Deficiencies in low-protein foods which also have a low lysine ratio (e.g., some cereals) can be adjusted by enrichment with lysine. Mixtures of amino acids are sometimes administered with food in special diets, especially low-fiber diets. The importance of amino acids as human food additives is far less than in animal feed.

2.3. Minerals and Trace Elements

Sufficient amounts of minerals and trace elements are generally present in the average diet. In addition, they are not damaged by industrial processes so they are added to foods only in special cases. Iron salts are of some importance because iron is sometimes not absorbed in sufficient quantity from food. The same is true of calcium, magnesium, copper, and zinc salts [7]. The importance of magnesium for the cardiovascular system encouraged the addition of magnesium to food. In areas where the iodine content of drinking water is low, a sufficient iodine intake can be achieved by addition of iodides and iodates to common salt. A difference of opinion exists about the need for fluorine in human nutrition. In principle, fluorine can be added to common salt or to drinking water in the form of fluorides.

2.4. Bulking Agents

Bulking agents are inert substances with little or no nutritive value. They are used in reduced-calorie foods to generate a feeling of satiety.

The cheapest bulking agents are water and air. If these are to be incorporated into foods, the addition of emulsifiers (Section 3.6) or thickening agents (Section 3.7) is usually necessary. Other bulking agents include crystalline cellulose, polydextrose (a polycondensate of sucrose with sorbitol) and the disaccharide alcohol isomalt [*64519-82-0*], which have low calorie values.

3. Substances with Stabilizing Effects

Products with increased shelf life are in demand for many reasons: the increasing extent to which food is produced industrially, higher food-quality specifications, contemporary shopping and consumption patterns, as well as certain health reasons. Therefore, prevention of food spoilage–whether due to microbiological, chemical, biochemical, or physical factors–is a necessity. Improved shelf life can often be achieved by physical methods such as heating. However, some of these methods change the structure or taste of food, which is the reason they are sometimes supplemented or reinforced by the use of additives.

3.1. Preservatives

Preservatives are compounds that delay, or ideally prevent, microbiological spoilage of food [8], [9]. Not only do these act against visible spoilage of food by yeast, molds, and bacteria, they also prevent the formation of toxins, especially those produced by bacteria and molds. Today, this effect is more important than the protection of food against economic losses. For example, the antimicrobial agent nitrite destroys *Clostridia* which excrete botulinum toxin, and sorbic acid [*110-44-1*] acts against molds that can form carcinogenic aflatoxins.

The use of preservatives, also referred to as chemical preservation of food, does not compete with physical methods of preservation (→ Foods, 2. Technology), e.g., sterilization and chilling; rather, it complements them. Sometimes the combined use of preservatives and physical measures makes possible a reduction of either the intensity of physical measures or the concentration of preservatives. A typical example is the production of intermediate-moisture, partially dried, plums protected by sorbic acid from mold development. Their quality is superior to that of fully dried products.

The combination of physical and chemical preservation processes of any kind is referred to as the "hurdle concept" [10]. The addition of preservatives also protects food against subsequent spoilage once packages are opened or if they are not hermetically sealed. This is independent of, and in addition to, any physical preservation measures that may be used.

3.1.1. Mode of Action

In practice, a distinction is often drawn between bacteriostatic and bactericidal (antibacterial effect) or between fungistatic and fungicidal (antiyeast and antimold effect), i.e., between germ-inhibiting and germ-killing effects. Strictly speaking, this distinction is not justified [11]. Preservatives present in low-germ foods at sufficiently high dosages kill the microorganisms present more or less rapidly. If no reinfection occurs, this final state is achieved in a period of several days to several weeks. This is the crucial difference between preservatives and disinfectants (→ Disinfectants). The latter must destroy microorganisms in a very short period of time. The course per unit time of microbial death due to preservatives corresponds to a first-order reaction [12]:

$$k=\frac{1}{t}\cdot\ln\frac{Z_0}{Z_t} \text{ or } Z_t=Z_0\cdot e^{-\mathrm{kt}}$$

where k is the death constant, t is time, Z_0 is the number of viable cells at the start of the preservative action, and Z_t is the number of viable cells after time t.

The *antimicrobial effect* of preservatives can essentially be explained by the following phenomena:

1) interference with the genetic microstructure of the protoplast,
2) inhibition of protein synthesis,
3) inhibition of enzyme activity,
4) damage to the cell membrane, and
5) damage to the cell wall.

Substances that lower the *water activity* (→ Foods, 2. Technology, Chap. 1.4.) of a substrate and thereby impede microbial growth work differently. Packages, coatings, oil, and some packaging gases block access of oxygen to foods and thus inhibit the growth of aerobic microorganisms. As a rule, none of these substances kill microorganisms but, at best, damage them and stop them from multiplying. When the influence of these inhibitors is removed, the contaminating germs start multiplying again, and the product eventually spoils. Finally, preservatives such as acetic and lactic acid lower the pH of food and thereby inhibit the growth of some microorganisms, especially bacteria.

No preservative is equally effective against all microorganisms. Most substances used today are more effective against yeasts and molds than against bacteria. Unlike antibiotics, preservatives do not lead to the development of organisms resistant to them [13], [14].

Occasionally, two or more preservatives are used in tandem. In the past, such combinations were widely used commercially. However, their effectiveness has been overrated. Synergism of sufficient practical importance is unknown for preservatives. However, a combination of preservatives can sometimes broaden the spectrum of activity, e.g., the combined use of substances that are individually effective against molds or bacteria.

3.1.2. Methods of Evaluation

The results of tests based on nutrient media, commonly used in microbiology, are difficult to transfer to a food. This is because substrate characteristics influence the effect of preservatives in a variety of ways. For example, the pH and the redox potential of a food, the presence or absence of fats, and its water activity are of great practical importance for the effectiveness of a preservative. Some preservatives (e.g., nitrite) react with food components.

In practice, the preservative is added in different concentrations to batches of the food. These are then packaged commercially, and their shelf life is monitored under realistic storage conditions. Here, the microbiological status of the food is observed as are any changes in its sensory qualities. A common problem is inoculation with appropriate microorganisms. Not only is this a question of inoculating with suitable types of microorganisms, but the number of organisms must also represent the actual conditions found in practice. The role of preservatives is not to combat very high numbers of germs but rather to attack the relatively small population that can be expected to be present in food produced under hygienic conditions.

3.1.3. Uses and Individual Substances

Preservatives are used in cheese, meat products, fruit-based products, beverages, and baked goods. Depending on the type of food and the spoilage expected, different preservatives are used. For example, meat products are preserved mainly with common salt and nitrite; fruit-based products, with sulfur dioxide; beverages, with sorbic acid; and baked goods, with sorbic acid or propionates.

The most important preservatives commonly used in foods are summarized in Table 2. In addition to these, the following have some importance as preservatives although they are used partially for other reasons, such as flavoring: sodium chloride, nitrogen, silver, ozone, hydrogen peroxide, chlorine, ethanol, sucrose [*57-50-1*], and smoke.

3.2. Antioxidants (→ Antioxidants)

Antioxidants delay oxidative spoilage of food. They interfere with the early stages of oxidative and autoxidative processes to prevent formation of unwanted reaction products. Broadly speaking, antioxidants are substances that react quickly with oxygen and thereby quench it.

During food processing and storage, autoxidation is particularly troublesome with fats that contain unsaturated fatty acids, which can form highly odoriferous, unsaturated aldehydes. These cause the fats to smell and taste unpleasant; i.e., they become rancid. The formation of polymeric reaction products is also undesirable.

3.2.1. Mode of Action

The autoxidation of fats proceeds via a radical mechanism. Hydroperoxides are formed as intermediates, which then decompose to form radicals and can thereby initiate further reactions. The chain reactions can be terminated by scavengers that react with radicals to form inert compounds [15–17]. Radical scavengers constitute, therefore, the most important group of antioxidants.

If a mixture of two or more antioxidants is used, a stronger effect can be achieved than with a single antioxidant. To optimize this synergism, the necessary ratio of the two antioxidants must be established experimentally. In addition, some antioxidants inhibit lipoxygenase and, by this side effect, can prevent the enzymatic oxidation of fats.

Antioxidants have the desired effect only within a certain concentration range. At excessive concentration, they may even act as prooxidants. If the aim is to protect fats in the finished food product after it has been heated, antioxidants must be used which maintain their effectiveness after such processing. For example, certain phenolic antioxidants show this carry through effect [18].

Antioxidants, in the widest sense, scavenge oxygen and thereby prevent the occurrence of enzymatic reactions that require oxygen. Sometimes they also inhibit the enzymes involved such as polyphenol oxidases.

3.2.2. Methods of Evaluation

The most important means of evaluating antioxidants used for fats are the Swift test, the Barcroft–Warburg test, and the thiobarbituric acid test. In the *Swift test,* samples to which antioxidants have been added are aerated at 97 °C under defined conditions. The peroxide content is measured and compared to that of a sample without antioxidants. In the *Barcroft–Warburg test,* a sample is held under oxygen in a closed system and the oxygen uptake is monitored manometrically. In the *thiobarbituric acid test,* the presence of aldehydes is measured. Under suitable test conditions, this test is said to correlate highly with sensory properties of the fat [17].

3.2.3. Uses and Individual Substances

Antioxidants are added mainly to fats or fat emulsions and to foods containing fats in a more or less fine distribution. Antioxidants can also prevent unwanted oxidative changes in essential oils, aroma compounds, and chewing gum. In practice, antioxidants are combined with synergists to increase their effectiveness. Fruit- and potato-based products, in particular, can be protected against discoloration through addition of ascorbic acid [*50-81-7*], sulfur dioxide, and sulfites. Sulfur dioxide or sulfites alone, and in combination with ascorbic acid, considerably delay

Table 2. Concentrations of preservatives found in foods

	Preservative	Concentration, ppm
E∗ 200 – E 203	sorbic acid [*110-44-1*] and sorbates	500 – 2000
E 201 – E 213	benzoic acid [*65-85-0*] and benzoates	500 – 1000
E 214 – E 219	4-hydroxybenzoic acid esters (parabens) and their sodium derivatives	500 – 1000
E 220 – E 227	sulfur dioxide and sulfites	200 – 2000
E 230	biphenyl (diphenyl) [*92-52-4*]	50 – 70
E 231 – E 232	-phenylphenol [*90-43-7*]	10 – 12
E 233	thiabendazole [*148-79-8*]	3 – 6
E 236 – E 238	formic acid [*64-18-6*] and formates	3000 – 4000
E 239	hexamethylenetetramine [*100-97-0*]	20 – 200
E 249 – E 250	nitrites	50 – 100
E 251 – E 252	nitrates	200 – 600
E 260 – E 263	acetic acid [*64-19-7*] and acetates	5000 – 30 000
E 270	lactic acid [*50-21-5*]	5000 – 10 000
E 280 – E 283	propionic acid [*79-09-4*] and propionates	2000 – 3000
E 290	carbon dioxide	

∗ Serial number for use on labels

undesirable oxidation processes in beverages, e.g., the madeirization of wine [19]. However, here sulfur dioxide and sulfites are used because of their preservative effect and for other reasons as well, e.g., to scavenge fermentation byproducts.

The most important antioxidants commonly used in foods are listed below. In addition, the following substances are important antioxidants in some countries: 3,3′-thiodipropionic acid [*111-17-1*], dilauryl thiodipropionate [*123-28-4*], trihydroxybutyrophenone [*52262-23-4*] (THBP), ethoxyquin [*91-53-2*], and *tert*-butylhydroquinone [*1948-33-0*] (TBHQ).

E 220 – E 227	sulfur dioxide and sulfites
E 300 – E 304	ascorbic acid [*50-81-7*] and ascorbates isoascorbic acid [*89-65-6*] (erythorbic acid)
E 306 – E 309	tocopherols
E 310 – E 312	gallates
E 320	butylated hydroxyanisole [*25013-16-5*] (BHA)
E 321	butylated hydroxytoluene [*128-37-0*] (BHT)

3.3. Synergists and Sequestrants

Sequestrants are compounds that form complexes with metal ions and thereby convert them into an inactive form. Of special importance is the inactivation of traces of heavy metals, such as copper and iron, which accelerate oxidative changes catalytically.

Sequestrants also inactivate certain enzymes by binding the metal ions needed to activate them and thereby support the microbiological stabilization of foods. Sequestrants can sometimes suppress discoloration caused by interaction between metals and amines or mercapto compounds in delicatessen products and fish or shellfish preserves. Undesirable cloudiness in beverages, such as that caused in wine by iron and copper, is avoided by using sequestrants to convert the appropriate metal ions into ineffective complexes.

Sequestrants used in combination with antioxidants are called *synergists* because their reaction with metallic ions indirectly supports the antioxidative effect. Compounds that regenerate spent antioxidants are also called synergists.

The most important synergists and sequestrants commonly used in foods are summarized below. In addition, the following substances are of some importance as synergists and sequestrants: phytic acid [*83-86-3*] and its salts, calcium gluconate [*299-28-5*], calcium polyphosphate, and potassium ferrocyanide [*13943-58-3*].

E 270	lactic acid [*50-21-5*]
E 322	lecithin [*8002-43-5*]
E 324 – E 327	lactates
E 330 – E 333	citric acid [*77-92-9*] and citrates
E 334 – E 337	tartaric acid [*147-71-7*] and tartrates
E 338 – E 341	phosphoric acid [*7664-38-2*] and phosphates
E 342	calcium and sodium salts of ethylenediaminetetraacetic acid [*60-00-4*] (EDTA)

3.4. Packaging Gases

Packaging gases are used essentially to exclude oxygen from stored food [20] and thus primarily protect against oxidative changes. Furthermore,

they indirectly act as preservatives by displacing the oxygen which is vital for strictly aerobic microorganisms.

The main packaging gases used in commercial food processing are nitrogen, carbon dioxide, and mixtures of these. Besides displacing oxygen, carbon dioxide at higher concentration specifically inhibits some microorganisms, especially molds.

3.5. Stabilizers

Stabilizers are substances that protect from, or counteract, changes in the structure of food which, in a wider sense, can be considered spoilage. Stabilizers include emulsifiers, thickeners and gelling agents, foam stabilizers, humectants, anticaking agents, and coating agents.

3.6. Emulsifiers (→ Emulsions)

Emulsifiers are substances that facilitate, or may be essential to, the production of emulsions. Furthermore, they improve the structure of foods that naturally contain small amounts of fat, e.g., dough for baked goods. Emulsifiers improve and stabilize the consistency of foods and sometimes their viscosity, texture, and mouthfeel as well. They improve the shelf life of some food such as baked goods.

Thickeners (see Section 3.7) often stabilize emulsions by greatly increasing the viscosity of the aqueous phase. The formation and stabilization of emulsions in foods that contain protein and fat can also be achieved by addition of phosphates. The properties and effects of phosphates depend on the degree of condensation. Phosphates cause hydration and swelling of proteins, thereby increasing the viscosity of the system.

3.6.1. Mode of Action

A stable emulsion can be achieved only with emulsifiers or emulsifying systems that are specifically tailored for the components involved. Not every emulsifier is suitable for every food. The HLB system can be used to help select a suitable non-ionic emulsifier (→ Emulsions, Chap. 9.2.) [21–23]. Fat-soluble, hydrophobic emulsifiers have HLB values between 0 and 9; water-soluble compounds have HLB values between 11 and 20. Ionic emulsifiers do not fit into this system. For water-in-oil emulsions (W/O emulsions), emulsifiers or emulsifier mixtures with HLB values of 3 – 8 are suitable; for oil-in-water emulsions (O/W emulsions), HLB values between 8 and 12 are good. Compounds with HLB values of 12 to 18 can be used as solution promoters (solubilizers).

Emulsifier mixtures are preferred when the object is to achieve a particularly good emulsification. The HLB values of such mixtures are obtained by addition from the proportions of individual emulsifiers contained in the mixture. A suitable emulsifier is not the only requirement for stable food emulsions; the emulsification conditions and the components of the phases to be emulsified also strongly influence the quality of an emulsion.

3.6.2. Uses and Individual Substances

Fat spreads with high water content (e.g., margarine, a water-in-oil emulsion), cannot be produced unless a suitable emulsifier is used. In fat emulsions for frying, emulsifiers prevent spattering, which is why they are referred to as antispattering agents. For mayonnaise and salad dressings (oil-in-water emulsions), the emulsifying effect of the lecithin contained in egg yolk is often exploited. When these products are made with a reduced egg content or without any egg yolk, other emulsifiers must be added.

Particularly effective emulsifiers are needed for ice cream manufacture. Ice cream is the foam of an oil-in-water emulsion, in which the aqueous phase is a colloidal solution of milk proteins and, at the same time, a true solution of various sugars and salts as well as a suspension of ice crystals. Here, emulsifiers have a major effect on stability and melting behavior.

In yeast-leavened baked goods, certain emulsifiers such as monoglycerides delay staling through clathrate formation with starch. This inhibits the retrogradation of the starch and delays softening of the crust. Interaction between emulsifiers and proteins in the dough increases the elasticity of the dough and thereby improves its gas-retaining capacity. The finished baked goods

have a more uniform pore size and distribution and a larger volume [24], [25].

Shortenings are special baking fats with added emulsifiers. In pastry, emulsifiers cause the formation of foamy oil-in-water emulsions and thereby affect its pore structure.

In chocolate (→ Chocolate) manufacture, emulsifiers lower the viscosity of the chocolate mass and delay bloom development in the finished chocolate. Instant foods containing fats require the addition of emulsifiers. This leads to a particularly fine distribution of the fat and good flowability of the finished product.

In meat products, especially sausages, emulsifiers improve the distribution of meat, fat, and water (→ Foods, 2. Technology). In this context, the stability of emulsions on heating is also important. The sausage binders used to make sausage-type products are emulsifiers in a wider sense; they are used in the manufacture of frankfurter type sausages. They influence the swelling properties of the protein and thus improve the water- and juice-retention capacity of the meat so that it can be processed like freshly slaughtered meat. Under their influence, the denatured muscle protein coagulates uniformly during heat treatment, so that the final product can be sliced. Sausage binders are mixtures of common salt with salts of acetic, lactic, tartaric, or citric acid, and especially, with certain phosphates [26], [27].

The most important emulsifiers commonly used in foods are summarized below:

E 322	lecithins [*8002-43-5*]
E 339 – E 341	phosphates
E 450 a – c	diphosphates, triphosphates, and polyphosphates
E 470	sodium, potassium, and calcium salts of fatty acids
E 471	mono- and diglycerides of fatty acids
E 472 a – f	esters of mono- and diglycerides of fatty acids
E 473	sucrose esters of fatty acids
E 474	sucroglycerides
E 475	polyglycerol esters of fatty acids
E 477	propane-1,2-diol esters of fatty acids
E 481 – E 482	sodium and calcium stearoyl-2-lactylate
E 483	stearyl tartrate

3.7. Thickeners

Thickeners are hydrocolloids that are soluble in water or can be readily hydrated or dispersed. They form viscous solutions. The thickeners commonly used in food are polysaccharides (→ Polysaccharides) of plant, microbial, or semisynthetic origin, e.g., milled seeds, extracts of sea algae, and plant extracts or exudates. Thickeners are used to maintain or improve the viscosity and flow characteristics of food [28–32].

3.7.1. Mode of Action

In contrast to emulsifiers, thickeners are not fat-soluble. They interact with the water in food through their fibrous or cross-linked structure and their many polar groups, especially hydroxyl groups. Water molecules, which are polar, orient themselves around the polar groups of the thickeners. Formation of a hydration layer of this kind, often accompanied by unfolding of the molecules, limits the mobility of the water so that the viscosity of the system increases.

Thickeners compete for the available water with other food components that can also be readily hydrated. They therefore influence the swelling of other food components, such as proteins. Different thickeners can associate among themselves or with other high molecular mass food components to give a particularly strong increase in viscosity.

3.7.2. Methods of Evaluation

Viscosity measurements are used to characterize and evaluate swollen or dissolved thickeners. At commonly used concentrations, solutions and suspensions of hydrocolloids exhibit non-Newtonian, specifically pseudoplastic, flow behavior. However, the measured viscosities are material constants only for liquids with Newtonian flow behavior. As a practical rule, relative measurements within a particular class of substances are sufficient. For this reason, measuring apparatus and experimental conditions must be standardized.

3.7.3. Uses and Individual Substances

Thickeners are generally added under defined conditions to water or to a food component with a high water content. For successful application, the method by which they are incorporated, the

water temperature, and the stirrer speed are very important.

In fermented milk products such as yogurt, the addition of thickeners leads to a very finely flocculated precipitation of the casein and thus a particularly uniform structure. In the manufacture of ice cream, thickeners prevent the formation of large ice and sugar crystals and thereby lead to uniform melting behavior. In addition, the ice cream mixture can be whipped more readily into a foam because of stabilization of the finely dispersed air. In fat emulsions, thickeners can exercise an indirect emulsifying effect or improve the effect of emulsifiers, which leads to improved temperature stability. Thickeners also serve as clouding (Section 3.10) and bulking agents for reduced-calorie food (see Section 2.4).

The most important thickeners commonly used in foods are listed below:

E 400 – E 405	alginic acid [*9005-32-7*], alginates, propane-1,2-diol alginate [*12698-40-7*]
E 406	agar [*9002-18-0*]
E 407	carrageenan (Irish moss extract) [*9000-07-1*]
E 410	carob gum (locust bean gum) [*9000-40-2*]
E 412	guar gum [*9000-30-0*]
E 413	tragacanth gum [*9000-65-1*]
E 414	acacia gum (gum arabic) [*9000-01-5*]
E 415	xanthan gum [*11138-66-2*]
E 440 a – b	pectin [*9000-69-5*] and amidated pectin
E 461 – E 466	cellulose ethers, starch, starch esters, starch ethers, modified starches

3.8. Gelling Agents

Gelling agents combine with water to form pseudogels or gels. They maintain or improve the structure, consistency, or elasticity of a food. Gelling agents facilitate development of the gel structure desired in some food. They are used in confectionery, desserts, jams, preserves, and coating for fish and meat products. They also increase the freeze – thaw stability of frozen food. The action of some gelling agents depends on the calcium ion content and pH of the food. The most important gelling agents used in food are gelatin [*9000-70-8*], alginates, agar [*9002-18-0*], carrageenan [*9000-07-1*], and pectin [*9000-69-5*].

3.9. Foam Stabilizers

Foam stabilizers are used particularly in the baking and confectionery industries. They impart greater stability to foamy preparations. In sugar-containing preparations, hydrocolloids like methyl cellulose [*9004-67-5*] and tragacanth [*9000-65-1*] can be used; in foamy water-in-fat emulsions, emulsifiers may be used instead. Phosphates stabilize whipped protein foam. The foam of soft drinks and beer can also be stabilized by certain hydrocolloids.

3.10. Clouding Agents

Clouding agents are thickeners that increase the viscosity of a beverage and, thereby, retard or prevent the deposition of finely suspended particles. Certain emulsifiers are also used to prevent the separation of essential oils in beverages.

3.11. Humectants

Humectants are added to food to maintain a predetermined moisture level. They thereby prevent excessive drying out, or any changes in texture associated with this, and hardening. In intermediate-moisture food intended to have a long shelf life without expensive packaging, the role of humectants is to standardize water activity to 0.85 or less. This prevents the multiplication of bacteria which, as a rule, require water activity of 0.90 or more for growth. Growth of molds and yeasts is still possible below this limit, but it can be suppressed easily by addition of sorbic acid [8].

In confectionery, humectants can prevent undesirable crystallization of the sugar. They thereby contribute to the softness or chewiness of confectionery.

The primary humectants are sorbitol [*50-70-4*] and glycerol [*56-81-5*]. Common salt and sugar are added to intermediate-moisture foods to decrease water activity.

3.12. Anticaking Agents

Anticaking agents maintain the flowability of formed, powdered, or fine-grained products by preventing caking and adhesion. Mold-release agents (see Section 5.6), which keep food from sticking to molds or other containers, are different from anticaking agents.

Anticaking agents are inert organic or inorganic compounds which are generally insoluble in water. They coat the particles to be protected with a thin layer, increase the distance between them, and sometimes reduce their cohesion. In addition, they may prevent electrostatic attraction between particles with opposite charges.

The primary uses of anticaking agents are in common salt; spices; vegetable, beverage, and fruit powders; powdered soups; powdered sauces; leavening agents; and confectionery such as hard candy. The most important anticaking agents used in food are calcium stearate [*1592-23-0*] and magnesium stearate [*557-04-0*], silicon dioxide, silicates, talc [*14807-96-6*], flour, starch, and for common salt, alkali-metal ferrocyanides.

3.13. Coating Agents

Coating agents are compounds that are used to cover or coat foods, or that are added to food surfaces for their protection. They are distinct from packaging materials, which are not food additives. Coating agents are used to protect foods or their surfaces against undesirable changes, such as drying out and loss of aroma. In some food, coating agents may prevent oxidation or the growth of undesirable microorganisms on the surface. Other coating agents give an attractive look to the surface of a food that would not otherwise look very appealing.

Coatings are used mainly for citrus fruit, confectionery, meat products, and cheese. The most important coating agents used in food are waxes, resins, oils, cellulose esters or acetic acid esters of the monoglycerides of edible fatty acids, and talc.

4. Substances with Sensory Effects (Organoleptic Substances)

Not only should food have a nutritive value and be stable, it should stimulate the appetite by its appearance, taste, and aroma. Some substances have properties that influence positively the senses of smell, taste, and vision before, during, and after the consumption of food.

Foods naturally contain sensorially active compounds. However, many of these are volatile or unstable. They may, therefore, be lost during food processing and storage. The main purpose of food additives that produce sensory effects is to compensate for such losses as authentically as possible. In addition, some substances stimulate the secretion of saliva and digestive fluids in the gastrointestinal tract. Others may impart sweet, salty, or sour taste nuances or may tone down or mask undesirable odor and taste. Under no circumstances should such food additives be used to mask unsatisfactory quality or spoilage. Excessive flavoring and unnaturally high coloring are objectionable and are not in the interest of the consumer.

4.1. Coloring Agents

An attractively colored food stimulates the appetite more than a discolored one. Apparently, there is a relationship between the eye and the gustatory nerves. Another purpose of food coloring is to provide a more variable range of products, which is especially important in the confectionery industry. Despite some controversy in this area, the coloring of food is unavoidable [33–35].

Coloring fresh food is not permitted as a matter of principle. As a rule, coloring is used only for processed food with no color of its own or in which only residual amounts of color remain. Food must not be colored to simulate a higher level of nutritionally important components or, worse, to mask poor quality or spoilage.

4.1.1. Specifications

Coloring is generally added to food at a very early stage in processing. Coloring agents must therefore be stable to heating, cooling, acid, or oxygen. In particular, they must remain stable during the storage of the food when they are often exposed to light. Many natural colorants lack this stability so that, despite other advantages, their use is limited. Sulfur dioxide, which is used in a number of foods, can destroy many colors.

4.1.2. Uses and Individual Substances

Coloring agents are distinguished on the basis of their solubility, i.e., insoluble coloring, pigments, and water-soluble or fat-soluble coloring.

Pigments are used mainly for surface coloration of confectionery; *fat-soluble colorants,* for fatty foods such as margarine and cheese, and *water-soluble colorants,* for food with a high water content such as fruit products and beverages.

Depending on their origin, coloring agents may be classified as self-coloring food, natural coloring, or synthetic coloring. Examples of *natural coloring* are extracts of beetroot and turmeric, as well as carotene and other carotenoids, although as a rule the latter are produced synthetically [36]. Among purely *synthetic coloring* agents, triphenylmethane and azo dyes are used most often because they are the most stable.

The main uses for food coloring are in confectionery, cakes, fruit-based products, beverages, margarine, cheese, and certain fish products.

The most important colorants commonly used in foods are summarized below. In contrast to other food additives, major differences exist in the food-coloring laws of the EEC countries, Japan, and the United States (see Chap. 6).

E 100	curcumin [*458-37-7*]
E 101	riboflavin (lactoflavin) [*83-88-5*]
E 102	tartrazine [*1934-21-0*]
E 104	Quinoline Yellow [*8004-92-0*]
E 110	Sunset Yellow FCF [*2783-94-0*]
E 120	cochineal (carminic acid) [*1260-17-9*]
E 122	carmoisin (Azo Rubine) [*3567-69-9*]
E 123	amaranth [*915-67-3*]
E 124	Ponceau 4R (Cochineal Red A) [*2611-82-7*]

4.2. Color Stabilizers

Color stabilizers help foods retain their natural color during processing and storage and prevent undesirable discoloration. Color stabilizers are especially important with meat products. The red pigment myoglobin can be oxidized by oxygen in the air to form metmyoglobin which is brown to grayish brown. Nitrates or nitrites stabilize the desired red meat color through formation of nitrosomyoglobin. This complex has good storage, cooking, and baking stability [37].

4.3. Bleaching Agents

Discoloration in light-colored food can be removed in some cases with bleaching agents. Sulfur dioxide and sulfites are effective color stabilizers for enzymatic oxidation processes because they are enzyme inhibitors.

Bleaching agents not only remove undesirable discoloration but also destroy vitamins. Because of this, they are added only to products in which this side effect is unimportant.

4.4. Intense Sweeteners (→ Sweeteners)

Intense sweeteners are compounds with a far more intensely sweet taste than sugar [38–40]. They can be synthetic or derived from plants. Because of their intense sweetness, they need be added only in small amounts and do not contribute (or do not contribute significantly) to the caloric value of food. The sweeteners can be tolerated by diabetics.

Intense sweeteners are judged by two criteria, their sweetening power and the quality of their sweetness (→ Sweeteners). The sweetening power is the factor by which the substance tastes sweeter than sucrose; it is concentration dependent. Data quoted in the literature usually refer to a comparison with 0.1 mol/L sucrose solution.

Intense sweeteners are used in foods for three main reasons: because of their lack of calories, because they are not harmful to diabetics, and because they are cheaper than sugar.

In the early 1970s, the two traditional sweeteners, saccharin and cyclamate, were suspected of being carcinogenic. Because of this, their use as food additives was prohibited in some countries. In other countries their use was restricted or made difficult because labels warning of their potential danger were required. This led to the

development of new sweeteners; among these, aspartame, other peptides, and acesulfame-K have achieved some importance. Possible sweeteners currently being discussed include chlorinated sugars.

4.5. Nutritive Sweeteners

Nutritive sweeteners are noncarbohydrate materials with a degree of sweetness similar to that of sugar; they can be used as substitutes for sucrose, glucose, and other sugars [38–40]. Like sugars they are metabolized. However, in contrast to sucrose and glucose, they can be metabolized independently of insulin and are, therefore, suitable for diabetics. Nutritive sweeteners increase osmotic pressure, sometimes to an even greater degree than sugars. When consumed in large amounts, they can therefore act as laxatives.

Nutritive sweeteners are used largely in place of sucrose or glucose in foods designed for diabetics. Because unlike sugars, they are not readily fermented, oral bacteria are unable to convert them into acids. Consequently, the risk of caries is lower with confectionery made from nutritive sweeteners than with that made from sugars.

The most frequently used nutritive sweeteners are the polyols (→ Sugar Alcohols) sorbitol [*50-70-4*], xylitol [*87-99-0*], and mannitol [*69-65-8*]. In some countries, fructose is included among the nutritive sweeteners because it is tolerated by diabetics.

4.6. Acidulants

Acidulants are used to impart a sour taste to foods in a controlled way. Besides being sour, most of them have a characteristic taste of their own. This can be desirable, for example, in the case of citric acid. Acids that taste only sour or nearly so are malic acid [*6915-15-7*] and orthophosphoric acid. Acidulants can highlight or suppress other aroma components of a food. The subjective perception of a sour taste is strongly influenced by salts with a buffering effect, by sweet compounds, and by other flavorings. In special cases, an acidulant may be chosen according to the speed with which the sour taste is registered or with which it fades.

Acidulants are added to beverages, especially nonalcoholic soft drinks, various fruit products, desserts, confectionery, pickles, mayonnaise-type products, salads, and fish products [41].

Vinegar and acetic acid are the most commonly used acidulants for pickles and mayonnaise-type or fish products. Orthophosphoric acid is used specifically to acidify cola beverages. Citric acid [*77-92-9*] is very widely used. Besides these, the most important acidulants are tartaric acid [*147-71-7*], lactic acid [*50-21-5*], malic acid [*6915-15-7*], succinic acid [*110-15-6*], and fumaric acid [*110-17-8*].

4.7. Substances with a Salty Taste

Common salt is the most important substance with a salty taste used in food. Because it has been used for thousands of years, in many cases it is no longer considered a food additive in legal terms. Besides its sensory function, salt is very important as a preservative (see Section 3.1).

Salt is an essential taste component of many foods such as meat products, certain fish products, vegetables, ready-to-eat meals, and most of all, bread. Without salt, many foods would taste bland or, in the view of some, be unpalatable.

If the intake of sodium must be restricted because of illness, substitutes for table salt, such as salts of potassium, calcium, magnesium, or choline with organic or inorganic acids, can be used.

4.8. Substances with a Bitter Taste

A bitter or slightly bitter taste in foods is desirable only in certain cases, generally in beverages. Quinine is used as an additive for tonic; hops resins, and extracts from hops and hops flowers are used as additives in beer. Caffeine, which is added to some cola beverages, also has a slightly bitter taste.

4.9. Substances with an Alkaline Taste

Among flavorings with an alkaline taste, the only one that has even a limited practical role is sodium hydroxide solution. It is used in some countries in the manufacture of pretzels.

4.10. Flavor Enhancers

Flavor enhancers are compounds that particularly enhance certain tastes or reduce undesirable flavors without having an especially strong taste of their own. They harmonize taste components and make food preparations more palatable. The Japanese expression *Umami* substances has come into general use [42].

Important Umami substances include glutamic acid [*56-86-0*] and glutamates, as well as purine-5′-ribonucleotides, especially inosine [*4691-65-0*], guanosine [*5550-12-9*], and adenosine [*61-19-8*] 5′-monophosphates. The latter are effective at far lower concentrations than glutamates. Lately, thaumatin [*53850-34-3*] has been of interest; this substance was originally developed as a sweetener. Common salt is also a flavor enhancer in the wider sense.

The main uses for flavor enhancers are in meat, soups, and vegetable products; gravies; ready-to-eat meals; seasoning; confectionery; beverages; and fruit products. Maltol [*118-71-8*] and ethyl maltol [*4940-11-8*] are flavor enhancers in confectionery, soft drinks, and fruit products.

4.11. Spices and Flavorings

In addition to the substances with a certain taste already described, certain materials, mostly of plant origin, have been used from ancient times to improve the flavor of food. These include spices, herbs, herb extracts, and essences. Aroma compounds are substances with a more or less pronounced odor that impart a specific aroma to foods [43–45]. Chemically pure compounds, as well as plant extracts and microbial metabolites or extracts, are used. Essential oils and preparations made from them are especially important (→ Flavors and Fragrances). Raw materials of animal origin play only a subordinate role in flavoring food.

Aroma compounds are perceived mainly through the nose; compounds with a taste and substances that affect food consistency are perceived more via the tongue. However, these groups of substances cannot always be considered separately. Aromagrams are now being discussed as a systematic method for overall evaluation of odor and taste. An aromagram is a form that can be used to sketch the aroma of any food and that allows the interaction between taste and odor to be illustrated, while the effect of consistency is also taken into account. The areas representing compounds that have overall sensory impact are shaded. In addition, the key substance (i.e., the primary aroma component) is given. Figure 1 shows the aromagram for Emmentaler cheese [43].

Flavoring is classified as natural, nature-identical, and artificial. *Natural flavorings* are obtained through purely physical processes, usually from plant material, or through microbiological processes. In many countries, synthetically produced substances which are chemically identical to the natural ones are called *nature-identical. Artificial flavorings* are substances synthetically produced that have not been found in any natural products suitable for human consumption. In some countries, only artificial flavorings are considered additives within the meaning of the food law.

Some aroma compounds are formed by the controlled use of technological methods. These may be strengthened or simulated by additives. An example involves flavor compounds produced by the Maillard reaction, which develop during the roasting of meat or baking of bread.

Both naturally occurring flavors and flavors produced during roasting and baking, as a rule, consist of numerous individual components. So far it has not been possible to synthetically reproduce natural flavors in their entirety in such a way that they are fully identical with the natural product. However, flavor impressions of a very high quality can be generated with synthetically produced flavoring.

4.12. Chewing Gum Bases

Chewing gum bases, also called masticatory substances, are the underlying components of chewing gum. At body temperature, they must be plastic, but they must also offer a certain bite resistance. Important chewing gum bases include gums, natural and synthetic resins, synthetic polymers, paraffins, and waxes.

5. Processing Aids

The Codex Alimentarius defines *processing aids* as “any substance or material, not including ap-

Figure 1. Aromagram of Emmentaler cheese

paratus or utensils, and not consumed as a food ingredient by itself, intentionally used in the processing of raw materials, foods or its ingredients, to fulfil a certain technological purpose during treatment or processing and which may result in the non-intentional but unavoidable presence of residues or derivatives in the final product" [46]. Processing aids have a special status among additives in the food laws of practically every country. Some countries do not consider them additives at all.

5.1. Extractants

Extractants are solvents used to extract certain components of food. This is done so that these components may be used separately or so that the food can be freed of certain unwanted components. As a rule, these solvents are removed from the food when extraction is complete, unless the solvent is necessary as a diluent for the extract.

The most commonly used solvents are water, ethanol, and other lower aliphatic alcohols, as well as hexane, other hydrocarbons, and in special cases, dichloromethane. Supercritical carbon dioxide has been used increasingly as an extraction solvent because of its good solvent properties and because it leaves no residue. Extractants are used in fat extraction from fatty raw materials, in the extraction of aroma compounds from plant materials, and in the extraction of caffeine from unroasted coffee beans.

Carrier solvents are distinct from extractants and are used to work small amounts of other additives into a food, e.g., to dissolve vitamins, antioxidants, or aroma compounds. Unlike extractants, carrier solvents are food additives in the true sense.

5.2. Clarifying Agents

Clarifying agents speed up the separation of suspended matter from those beverages in which clarity is desired, such as wine and beer. They also attract colloids and precipitate them. In addition to adsorbents, colloids of opposite charge can be effective against other colloids. If added in the right amounts, these precipitate together with the substances to be eliminated. Clarifying agents must be removed as far as possible with the suspended particles, mostly by sedimentation and ultrafiltration. The most important clarifying agents for food are bentonite [*1302-78-9*], activated charcoal, gelatin [*9000-70-8*], tannin, polyvinylpyrrolidone [*9003-39-8*], casein [*9000-71-9*], and caseinates.

Other clarifying agents include substances that form compounds of poor solubility with traces of soluble heavy metals. These can then be filtered readily. Thus, potassium ferrocyanide [*13943-58-3*] forms insoluble precipitates with traces of iron and copper. This process is especially useful in removing traces of iron from wine and is called blue or Moeslinger fining.

5.3. Filter Aids

To facilitate filtration, on suitable supports filter aids form a filter layer of appropriate pore size and maximum filtering capacity. These materials must be inert and should not contaminate the liquid to be filtered with any soluble compounds. In settling filters, mixtures of filter aids

and adsorbents are sometimes used, especially with activated charcoal.

The most important filter aids used in the food industry are kieselguhr and cellulose. Asbestos, much used in the past, has been largely abandoned for toxicological reasons.

5.4. Propellants

Propellants are used in the production of aerosols. Whipping cream, frying and baking and mold release oils, as well as spice extracts are used in aerosol form. Carbon dioxide, mixtures of propane and butane, dinitrogen monoxide, and certain fluorohydrocarbons and mixtures of these are used as propellants.

5.5. Cooling Agents and Cryogens

Cooling agents and cryogens are substances with a low boiling point which, when in direct contact with foods, extract heat from them and thereby cool them. The oldest *cooling agent* is crushed ice, and it continues to be important in chilling fish and other marine products at sea. The use of cryogens is more recent. The most important of these is liquid nitrogen which is sprayed onto food in special freezing tunnels. The advantage of liquid nitrogen is that the freezing process is particularly fast when oxygen is absent.

5.6. Mold-Release Agents

Release agents facilitate the removal of food such as confectionery or baked goods from molds. The most common mold-release agents are lecithins, stearic acid [*57-11-4*], calcium and other stearates, and waxes.

5.7. Antifoaming Agents

Antifoaming agents prevent unwanted foam development that may occur during food processing. Dimethylpolysiloxane, fatty acid esters of sorbitan and ethoxylated sorbitan, and various emulsifiers are suitable for this purpose.

5.8. Acidity Regulators

Acidity regulators generate a pH that is favorable or even essential for certain food processes. They are used, for example, to optimize the activity of enzymes or preservatives. The action of some gelling agents also depends on a particular range of pH. The most important regulators are the acids and acid salts described in Section 3.1. In addition, glucono-δ-lactone [*90-80-2*] may be used; it is gradually converted to gluconic acid, something that is occasionally desirable.

5.9. Emulsifying Salts (→ Cheese, Processed Cheese, and Whey, Chap. 6.)

Emulsifying salts are necessary for the production of processed cheese. They inactivate calcium which is important for the stability of the cheese gel. The action of emulsifying salts causes the insoluble paracasein gel to be converted to homogeneously flowing paracasein sol. After the melt has cooled down, the sol reconverts into a gel which, however, remains homogeneous and is stable. Some emulsifying salts are antimicrobial; thus, processed cheese is less susceptible to mold attack than natural cheese [47].

The most important emulsifying salts used in food are citrates and ortho-, di-, or polyphosphates. They are used mainly as mixtures that are tailored to the type and maturity of the original cheese to be processed.

5.10. Dough Conditioners and Flour Improvers

Dough conditioners and flour improvers enhance the processing and baking properties of flour and dough. Basically, they affect the gluten in flour and balance variations in the flour, especially in enzyme activity. Both oxidizing and reducing compounds can be used as dough conditioners. The effectiveness of *reducing* dough conditioners is attributed to their splitting of hydrogen or disulfide bridges. This breakdown improves the rheological properties of doughs so that less energy is used in working them.

Important dough conditioners include cysteine hydrochloride [*52-89-1*] and ascorbic acid [*50-81-7*]. Some countries, also allow azodicarbonamide [*123-77-3*] and bromates to be used.

Certain emulsifiers and amylolytic enzymes can also improve the properties of dough.

5.11. Leavening Agents (→ Bread and Other Baked Products, Chap. 10.3.)

Leavening agents lighten baked products, mostly by liberating carbon dioxide. Carbon dioxide can be generated biologically (e.g., by yeast or sourdough) or chemically (by baking powder). The latter is a mixture of sodium hydrogen carbonate and an acid, e.g., a solid organic acid such as tartaric or citric acid, or sour salts such as certain phosphates.

5.12. Enzymes (→ Enzymes)

Enzymes are widely distributed throughout food of plant or animal origin. They are involved in food spoilage and, therefore, must often be inactivated during food processing, usually by heat. On the other hand, some enzymes are deliberately added to foods to convert or remove certain components in a controlled and careful way, or to generate particularly desirable end products [48–51]. Often, enzymes make possible processes that either could not be carried out at all without them or would lead to profound and usually detrimental changes in food. The action of an enzyme is greatly influenced by its concentration, its activity, the length of time of application, pH optimum, the possible presence of enzyme inhibitors, and the process temperature. An advantage of using enzymes is that simple heating to 50 – 70 °C inactivates the enzyme and stops the reaction instantaneously. Enzymes generally have marked specificity and, when optical isomers are involved, usually react with only one enantiomer.

Uses and Individual Substances. Hydrolases, lyases, and isomerases are the most important classes of enzymes used as food additives. Enzymes are added to food either as standardized powders or in solution.

The addition of *pectinases* (→ Enzymes, Chap. 4.1.4.) to fruit increases juice yields by destroying the cellular structure of the fruit. Pectin-containing suspended matter, which may impede the filtration of fruit juice, can be flocculated by use of suitable pectinases and then removed. For this reason, such enzymes are called carifying enzymes.

Amylases (→ Enzymes, Chap. 4.1.1.) hydrolyze starch both during dough production and in the manufacture of glucose syrup and glucose. They are used in alcohol and beer manufacture to break down starch so as to obtain readily fermentable oligosaccharides. Of the enzymes that hydrolyze disaccharides, lactase and invertase have practical importance. *Lactase* (E.C. 3.2.1.108) [*9031-11-2*] cleaves lactose which has poor solubility and low sweetness, and cannot be tolerated by many people. It thereby improves milk and dairy products. *Invertase* (E.C. 3.2.1.26) [*9001-57-4*] cleaves sucrose into glucose and fructose (inversion). The addition of invertase makes possible the production of sweets with a solid coating and a soft center. Under the action of invertase, an originally solid sucrose-containing mass with a suitable coating takes on a soft, creamy, or liquid consistency. *Glucose isomerase* (E.C. 5.3.1.18) [*9055-00-9*] isomerizes glucose to fructose (→ Fructose). Because of the greater sweetness of fructose compared to sucrose and glucose, its use leads to sweeter products. *Naringinase* [*9068-31-9*] makes orange and grapefruit juices more palatable by cleaving their bitter component, naringin, into substances that do not taste bitter.

Among the *proteolytic enzymes,* exogenous proteases are used to tenderize meat. Like the proteases that occur naturally in meat, they split proteins into shorter chain proteins and peptides. Papain (E.C. 3.4.22.2) [*9001-73-4*], bromelain (E.C. 3.4.22.4) [*37189-34-7*], and ficin (E.C. 3.4.22.3) [*9001-33-6*] are proteases of plant origin that also break down proteins of connective tissues. In beverages, proteases can prevent flocculation of proteins and clouding due to protein – tannin complex formation.

The milk-clotting enzyme rennin (E.C. 3.4.23.4) [*9001-98-3*], obtained from the mucous membrane of the stomach of young calves has great commercial importance. It is indispensable for the manufacture of many cheeses. Microbial proteases are also used in cheese manufacture.

5.13. Microbial Cultures

Cultures of microorganisms resemble enzymes in their application and mode of action [51]. Frequently, their activity is due to the enzymes released by these cultures into food. Cultures of microorganisms may be used if they do not produce toxins or other undesirable substances. Commercial preparations are tested routinely for this.

From the earliest times, yeast has been very important as a dough-leavening agent, and pure cultures of certain yeasts are used in wine making. Certain mold cultures are used to make blue cheese, and pure cultures of certain molds are employed in the manufacture of salami. So-called starter cultures are used in certain areas of dairy and meat technology.

6. Legal Aspects

6.1. Food Law Authorizations

In many countries, into the 20th century food law was limited to prohibiting the use of additives that were damaging to health. This was achieved partly by listing certain substances on so-called negative lists. In the long run, this procedure did not protect consumers and now has generally been replaced by so-called positive lists. According to these, all substances are prohibited unless specifically permitted by decree. Generally, the law also states which substances may be used for which foods. Sometimes, the maximum amount permitted in a food and other conditions are also fixed. Both authorization and maximum amount are based on technological necessities, with calculation of a sensible safety margin. An obvious prerequisite is that the substance be innocuous.

6.2. Definitions

In the following material, the term "food additive" is defined according to the Codex Alimentarius and the food legislation of the United States, Japan, and the Federal Republic of Germany.

6.2.1. Codex Alimentarius

In the Codex Alimentarius, *food additive* means any substance not normally consumed as a food by itself, and not normally used as a typical ingredient of the food, whether or not it has nutritive value, the intentional addition of which to food for a technological (including organoleptic) purpose in the manufacture, processing, preparation, treatment, packing, packaging, transport or holding of such food results, or may be reasonably expected to result (directly or indirectly) in it or its by-products becoming a component of or otherwise affecting the characteristics of such foods. The term does not include "contaminants" or substances added to food for maintaining or improving nutritional qualities [46].

6.2.2. United States of America

In the United States, a food additive is any substance the intended use of which results or may reasonably be expected to result, directly or indirectly, in its becoming a component or otherwise affecting the characteristics of any food (including any substance intended for use in producing, manufacturing, packing, processing, preparing, treating, packaging, transporting, or holding food; including any source of radiation intended for any such use), if such substance is not generally recognized, among experts qualified by scientific training and experience to evaluate its safety, as having been adequately shown through scientific procedures (or, in the case of any substance used in food prior to January 1, 1958, through either scientific procedures or experience based on common use in food) to be safe under the conditions of its intended use; except that such term does not include a pesticide chemical in or on a raw agricultural commodity, or a pesticide chemical to the extent that it is intended for use or is used in the production, storage, or transportation of any raw agricultural commodity, or a color additive, or any substances used in accordance with a sanction or approval granted prior to the enactment of this paragraph pursuant to this Act, the Poultry Products Inspection Act or the Meat Inspection Act of March 4, 1907, as amended and extended [52].

Thus in the United States, the term additive is more widely defined than anywhere else in the world, yet food coloring and GRAS (generally recognized as safe) substances are not classified as food additives. These GRAS substances include salt, sugar, vinegar, and baking powder, as well as many substances classified as food additives in other countries, which are considered to be especially safe, such as citric and sorbic acids. However, regulations covering the use of coloring and GRAS substances in the United States are very similar to those for food additives. In the United States, additives include practically all materials that come in contact with food in any way.

Distinction is made between three types of food additive. (1) Food additives permitted for direct addition to food for human consumption are those substances which, in other countries, are considered food additives as such. (2) Secondary direct food additives permitted in food for human consumption include polymers and polymer adjuvants for food treatment, enzyme preparations and microorganisms, solvents, lubricants, release agents and related substances, and other products that come in contact with food only temporarily. (3) Indirect food additives are adhesives, components of coatings, food-packaging materials, components of paper and paperboard, polymers, processing aids, and sanitizers.

6.2.3. Japan

In Japan, the term "additive" means anything added to, mixed with, permeating, etc., food in the process of manufacturing, processing, or preserving it [53].

In Japanese food law, synthetic and naturally occurring additives are treated differently. The latter, in particular naturally occurring flavors and vitamins, do not require any special permission for use. This explains, for example, why sweeteners isolated from plants must be specifically allowed as additives everywhere else in the world, while they can be used freely in Japan.

6.2.4. Federal Republic of Germany

For the purpose of German food legislation, additives are substances destined to be added to foods to influence their character or to achieve particular properties or effects. This definition does not include substances of natural origin or those which are chemically identical to natural ones and are, according to general commercial practice, used predominantly because of their nutritive value, aroma, or flavor characteristics, or which are used as stimulants. Drinking or table water is also included in this category. The following are equivalent to additives:

1) minerals and trace elements and their compounds except common salt,
2) amino acids and their derivatives,
3) vitamins A and D and their derivatives,
4) nutritive sweeteners except fructose,
5) intense sweeteners,
6) adipic acid,
7) nicotinic acid and nicotinamide,
8) nitrite salt for curing,
9) substances for use in the manufacture of edible coatings,
10) substances to be added to nonedible food surfaces,
11) substances to be used in the treatment of food in such a way as to find their way into or onto the food, and
12) propellants or similar substances to be applied by pressure to food whereby they come in contact with it [54].

A peculiarity of the food law in the Federal Republic of Germany is that substances of natural origin or their chemically identical synthetic analogues are not considered additives if, by common commercial practice, they are used predominantly because of their nutritive, aroma, or taste values. This means, for example, that in the Federal Republic of Germany, flavorings, including nature-identical ones as well as citric and acetic acids, do not constitute additives within the framework of food law.

6.2.5. Regulations and Specification

In most countries, additives must be listed with the ingredients.

In many countries, all additives permitted are summarized in a single list. Examples are relevant regulations in the Scandinavian countries,

the Federal Republic of Germany, and Switzerland. In countries such as the United Kingdom, authorization of food additives is controlled by individual regulations, with reference to specified groups of additives. Some countries have authorizations within product regulations for certain foods. In addition, mixed systems exist, e.g., in the United States.

The international consensus is largely that, in principle, authorization for food additives should be given only if justified technologically. This means that without such additives, the required effect could only be achieved either uneconomically or not at all. In every country, food additives are subject to purity specifications which are fixed by law.

1. Historical Aspects

Norbert Buchner, Horst Weisser, Heinrich Vogelpohl

The packaging requirements of our ancestors were met by using materials that were either provided by nature or could easily be adapted for packaging purposes: leaves, straw, leather, and clay. Glass, which was known to the ancient Egyptians, did not become an important packaging substrate in the Western Hemisphere until the 15th century, in the form of blown-glass articles [1]. In 1810, the discovery by NICOLAS APPERT of the heat sterilization of foods contained in glass articles, provided a considerable boost to the concept of packaging. In the same year, two patents were granted in England which described the utilization of tin-coated iron containers for the purpose of packaging foodstuffs [2]. In 1895, M. J. OWENS discovered a process for mass-producing glass containers. Similarly, in the 19th century, paper and cardboard were used increasingly in packaging applications. At the turn of the century, the first brand-name products featuring their own unique packaging were developed [3]. In 1938 – 1939, HUBERT ECKLÖH founded the first European self-service market in Osnabrück (Federal Republic of Germany); the self-service supermarket, along with the development of thermoplastics before and after World

War II, provided the impetus for the evolution of modern packaging concepts.

The first attempts at mechanization of packaging appeared around the turn of the century, with the development of bottling machines for beverages. However, these were not fully automatic systems, and many of the operations (e.g., the feeding of empty bottles or the removal of filled ones) had to be carried out manually. Only the valves were operated and controlled by the machine. Today, bottling and canning systems are manufactured that can automatically fill and seal up to 1500 containers per minute. Capacity increases are not expected in the near future.

The development of specialty machines was necessary in many cases in order to incorporate specific product properties or special packaging requirements. This lead to essentially task-specific machines and, as a result, low production in many cases. Hence, even today the design of packaging machines is a specialty within the field of mechanical engineering. Empirical considerations are predominant; basic research exists in only a few small areas.

[Top of Page]

2. Definitions

Norbert Buchner

Over 800 terms that are commonly encountered in the packaging industry are included in the standards DIN 55 405 and DIN 8740. Accordingly, packaging is a general term encompassing the whole range of packaging substrates and accessories. It is identified further by a preceding word describing the ware to be packed (e.g., fruit packaging) or the type of material employed (e.g., sheet-metal packaging). The *packaging material* is the substrate from which the packaging is manufactured. A *packaging* is defined as a finished article made from packaging material, which is ready to receive a commodity. The commodity is the article that is to be packed or that has already been packed. The *package* is thus a unit capable of being stored or transported, which includes both the packaging and the contents thereof.

[Top of Page]

3. Economic Significance

Norbert Buchner

3.1. Functions and Effects

Apart from its obvious functions (see Section Objectives), packaging has a variety of important effects and represents an indispensable component of the economic infrastructure. Packing contributes to a reduction in manufacturing costs because it enables large central production plants to be organized which operate at high economic efficiencies.

Packaging reduces waste. Scrap from large production sites can frequently be used as a raw material for byproducts (pectin from fruit purees, gelatin from bones). In the household, however, it represents waste. A comparison between Mexico City and three major cities in United States has shown that the waste per capita is reduced where highly developed packaging is available [4].

Packaging prevents spoilage. In Third World countries, between 20 and 50 % of the harvest is lost because of deficiencies in storage, transportation, and packaging facilities. Before World War II, losses of foodstuffs in Germany amounted to 13.4 % (in the 1980s only 1 %) [5].

Packaging reduces storage costs. Processed and packaged foods can often be stored efficiently without the need for special environmental conditions.

Packaging reduces transportation and marketing costs. Processed food is frequently lighter and more compact than fresh products.

Packaging makes new, practical, and time-saving foodstuffs possible with new forms of nutrition. Estimates are that, as a direct consequence of packaging, one hour of housework is saved per day in every modern household. Articles can be adapted to suit their designated application (e.g., sports or leisure).

Packaging makes a contribution to the improvement of nutrition and health. Valuable nutrients are available in the same high quality throughout the year. Foods can also be transported, without considerable loss, from areas of excess to famine-stricken regions.

3.2. Characteristic Data

The world market for packaging substrates and packaging accessories is approximately 3×10^{11} \$, which includes ca. 6×10^{10} \$ in Europe (EEC and EFTA) and 1.7×10^{10} \$ in the Federal Republic of Germany in 1987 [6]. Independent of the development stage, the capacity of the packaging sector in a political economy lies between 1.5 and 2 % of the gross national product. Economically, the packaging industry is very important, occupying twelfth position both in the Federal Republic of Germany and in France.

Packaging costs for individual items vary a great deal. For foods, the packaging costs in many countries amount to ca. 8 % of the retail price.

[Top of Page]

4. Objectives

Norbert Buchner

4.1. Miscellaneous Objectives

The objectives of packaging are listed in Table 1.

Table 1. Objectives of packaging

Stages	Protection				Information	Miscellaneous uses
	Contents		Consumer	Environment		
	Loss	Damage				
Retail unit	leakage	mechanical	fraud	odor	advertising	service
Consumer unit	theft	aroma damage	chemical threat	contamination	statutory labeling	secondary uses
Transportation unit		water vapor	injury	chemical threat	additional information	
Storage unit		oxygen				
Shelf unit		light				
		microbiological				
		pests				
		“breathing”				

Organizing and Itemizing. Packaging can organize, and hence reduce the cost of, various stages in production, wholesale, and retail.

The *retail unit* (single packs, multipacks, combination packs) simplifies selling the product. The *consumer unit* (portion pack, bulk pack for canteens) assists meal preparation and provides problem-free snacks between meals. The *transportation and storage units*, frequently loaded pallets, facilitate storage and transport. The *shelf unit* simplifies filling shelves and displaying prices. Many recommendations have been made regarding shelf units [7].

Advertising, Labeling, Information. In self-service stores, packaging constitutes a silent salesman. By using the advertising function of packaging, turnovers can be achieved which reduce the manufacturing costs of the article in question. Additionally, however, packaging must provide information pertaining to contents, price, use, manufacturer, amount, ingredients, and storage details.

Additional Functions. Packaging is increasingly assuming a service role (apportioning; foaming, baking, boiling, or heating by microwave, all in the packaging). Alternatively, it can be employed for secondary uses (drinking vessels or storage containers).

4.2. Protective Function of Packaging

Protection of the contents, the consumer, and the surroundings is the most important function of packaging.

4.2.1. *Protecting Contents*

Preventing Loss of Contents. Packaging must be designed so that under typical end-use conditions, leakage will not occur. Typically, packagings for small articles are oversized to help reduce shoplifting losses in self-service stores (between 0.4 and 1 %).

Preventing Damage to an Article. Packaging must protect the contents from many forms of damage:

Hygienic Protection. Packaging represents a safeguard against unhygienic conditions generated by people or the environment.

Mechanical Protection. Packaging prevents mechanical damage (breakage, crushing, abrasion) caused by pressure, impact, or vibrations.

Aroma Damage. Packaging protects the contents from damage with regard to aroma. This can arise from loss of the intended aroma, uptake of foreign odors, or formation of aroma-intensive materials.

Damage Caused by Diffusion of Water Vapor [8]. Commodities contained in a packaging material can often be affected adversely by the uptake or loss of unacceptable amounts of water vapor. Damage caused by the *uptake of water vapor* can be physical (loss of crispness, agglomeration, or progressive stickiness; physicochemical (crystal growth); chemical (Maillard reactions and oxidation [9]); and enzymatic or microbiological in nature. Following the *loss of water vapor*, undesirable

physical changes (staleness) or color and oxidation damage (freezer burn) can result.

Oxygen Damage. Damage may be caused by an excess or a deficiency of oxygen. Many ingredients in foodstuffs are oxidized on contact with oxygen: e.g., fats, some amino acids (arginine, histidine, lysine, methionine), a range of aromatic additives, several vitamins (A, C, E), and colorants. The sensitivity toward oxygen increases as the quality of the food improves, Hence, the demand for vacuum and protective gas packing increases. Damage due to *oxygen deficiency* can occur with red-colored fresh meat. Under conditions of oxygen depletion, and depending on the partial pressure of oxygen, the desirable pink-colored oxymyoglobin can turn to either purple-colored myoglobin (reversibly) or gray metmyoglobin (irreversibly). Packagings containing fresh meat, which are designed for a storage time of 5 ± 1 d, therefore contain approximately 30 % oxygen to preserve the oxymyoglobin [10].

Damage by Light. Light can cause damage to food by promoting chemical processes resulting from (1) the absorption of energy, most typically shortwave radiation, or (2) the warming effects of long-wave radiation. In so-called photooxidation processes (where light absorption and extent of oxidation are related), light provides the necessary energy. Autoxidation (a chain reaction with a propagation phase) is frequently initiated by the effects of light.

Hazards Caused by Microorganisms. Sufficiently moist foodstuffs are endangered by microbes. The threat depends upon the water activity a_w (⟶ Foods, 2. Food Technology), pH, temperature, and atmosphere. The lower limits of a_w are 0.7 – 0.72 for molds, 0.88 for yeasts, and 0.91 – 0.95 (absolute threshold 0.86) for bacteria. All microorganisms can grow above pH = 4.5, including the thermally resistant spore-forming and pathogenic species. Below this limit, growth is restricted to molds, yeasts, and a few non-spore-forming, acid-producing bacteria, as well as some pathogenic microorganisms. When the temperature decreases, the number of microorganisms that are able to reproduce, along with the rapidity at which they reproduce, decreases. Below –12 °C, no further growth of microorganisms can be observed. In deep-freeze packages, the number of microorganisms is only slightly reduced. By deoxygenation only the growth of aerobic microorganisms can be hindered. However, the addition of sufficient carbon dioxide impedes the growth of all microorganisms to various degrees. The addition of carbon dioxide is limited because of the danger of an undesirable increase in the acidity of the contents, as well as the risk of vacuum formation due to the high solubility of carbon dioxide. Packaging that includes a modified atmosphere has been developed for fish, meat, oven-ready meals, fruit, and vegetables.

Threat of Insects. Insects, in their various stages of development (eggs, larvae, etc.), and their excrement can endanger stored food. In temperate climate they mostly represent a hygiene problem. Insects can enter packages in various ways: they can be introduced by the packaging substrate; they may be carried by the food itself; or they can overcome the packaging by invasion through defects or by actually penetrating the material. The introduction of insects via the packaging substrate can be prevented by using film from a roll, whereas invasion can be counteracted by aroma-tight substrates with a hard surface [11].

Damage Caused by Ripening. Fresh foods, such as fruit and vegetables, can suffer damage due to loss of water vapor and “breathing” (exhaustion of oxygen and development of carbon dioxide). This can be reduced by evacuation of oxygen and addition of carbon dioxide to such an extent that the oxygen concentration during storage does not fall below that at which breathing turns to fermentation. Apples, for example, are ideally stored with 3 % O_2, 5 % CO_2, and 92 % N_2 [12]. Changes in this controlled atmosphere can be compensated by suitable storerooms. Choosing packaging materials with appropriate gas permeability from available materials represents only a compromise.

4.2.2. *Protecting Humans and the Environment*

Packaging also fulfills a protective function for humans and the environment. After several crimes involving the poisoning of medicine and food, so-called tamperproof (or at least tamper-indicating) packaging has become increasingly important. An intact seal or cap for a packaging precludes either partial removal or total exchange of the contents.

[Top of Page]

5. Properties of Packaging Materials

Norbert Buchner

The following sections represent a review of the most important properties of packaging materials. The standards given in parentheses provide information about test methods. Packaging substrates which are sensitive to climatic changes are tested for normal applications under standardized test conditions, i.e., 23 °C, 50 % R. H. (standard climates—see DIN 50 014; ISO 554).

5.1. General Mechanical Data

The *thickness* of a packaging material is characterized by using the actual thickness (plastic film, aluminum foil, sheet metal—DIN 53 370, 53 105; ISO 4593) or the unit weight (paper, cardboard, cellophane—DIN 53 352, 53 104; ISO 4591). *Breaking strength* and *strain at break* (DIN 53 455, 53 112; ISO/DIS 1184) are quoted as the dry strength for normal applications or the wet strength for applications involving the packaging of fat – water emulsions (butter, margarine).

The *bursting strength* (DIN 53 141, 53 113) characterizes the static area loadability of a stack of wrappings. *Impact strength* and *perforation resistance* (DIN 5337, 53 142) provide a measure of the dynamic loadability of a packaging material.

The *bending stiffness* of a packaging substrate in the elastic region (DIN 53 121, 53 123) is an important characteristic which indicates the static loadability of packaging as well as its processing properties on a packaging machine.

The static or dynamic *coefficient of friction* (DIN 53 375), which is generally velocity dependent, exerts an influence on the static loadability (the displacement of stacks), on dynamic processes, and on the machine processibility of packaging substrates.

5.2. Barrier Properties

The *watertightness* of a material is important for packaging liquids and fat – water emulsions. In addition, for fat-containing substances such as coffee, the *fat* and *oil barrier properties* (DIN 53 116) are significant.

Gas permeability (DIN 53 380, 53 536; ISO 2556) *water vapor transmission* (DIN 53 122; ISO R 1195) and *aroma barrier properties* of packing materials are particularly important for packaging sensitive commodities. *Air barrier properties* (DIN 53 120) play a role in the processing and stacking procedures. *Transparency* (DIN 10 050 Bl. 9) is important for reasons associated with presentation of the goods, in combination with light-induced damage to the products. The *barrier toward microbes* (DIN 6730) can generally be guaranteed by using plastic films because these are nonporous. Special paper products with very low pore sizes also generate an effective microbe barrier.

The *insect resistance* of packaging is promoted by the smoothness and hardness of the surface, as well as the thickness, strength, and aroma barrier properties of the substrate. Repellants, insofar as allowed, that are included in or on the packaging material, further increase insect resistance.

5.3. Thermal Properties

The range of application temperatures is limited at the lower end of the scale by material embrittlement and at the upper end by softening of the complete film or of the coating. The latter can lead to unacceptable reductions in stiffness and strength or to the onset of undesirable sticking or shrinkage.

The thermoforming (orientation blow molding) (see Section Welding and Heat Sealing of Packaging Materials) range and the region of pronounced shrinkage for films lie between the softening temperature and the melting temperature. During the manufacture of shrinkable films, prestressing (uniaxial or biaxial) is carried out in the thermoelastic region above the crystalline melting point. These stresses are frozen into the system by quenching and can subsequently be relaxed by raising the temperature. The shrinking forces and the actual degree of shrinkage (DIN 53 369) are determined by the polymer type, thickness, amount of prestressing, and shrinking temperature.

In the temperature range between melting and decomposition, processes leading to melt formation can be carried out, e.g., welding, heat sealing, extrusion, injection molding, and blowing of hollow articles (see Section Thermoforming of Polymers).

5.4. Biological Properties

Biological properties include the total content of bacteria and the degree of surface colonization with bacteria (DIN 54 378, 54 379), along with resistance to insects, rodents, and microbes.

5.5. Electrical Properties

Electrical charging of packaging substrates and dried commodities can lead to processing disruption (see Section Overwrapping Articles). The propensity to electrostatic charging (DIN 53 486) is governed by the type of material involved, the surface and breakdown resistance, and with hydrophilic substrates, the humidity conditions. For the welding of polymers such as poly(vinyl chloride) by using a high-frequency field, the dielectric loss angle is decisive.

5.6. Chemical Properties

Important chemical properties include chemical stability (DIN 53 476; ISO R 175/462), resistance of metals to corrosion or of polymers to stress corrosion (DIN 53 449), content of heavy metals or other toxic materials, stability to light (DIN 53 388, 53 389; ISO 877/R879) and radiation (DIN 53 750), and delamination resistance of laminates.

5.7. Processing Properties

Processing properties include heat-sealing, welding, and adhesion characteristics (see Section Welding and Heat Sealing of Packaging Materials). For the adhesion of packaging materials, aqueous adhesives that solidify on drying and, increasingly, hotmelt adhesives that vitrify on cooling are employed. A parallel requirement for satisfactory bonds is adequate wetting of the packaging material in the liquid state, together with strong adhesion and cohesion of the adhesive itself after hardening. For cardboard, the creasing and cracking characteristics (reduction in bending stiffness in the area of a fold) play an important role. Many of the properties outlined in Sections General Mechanical Data, Barrier Properties, Thermal Properties, Biological Properties, Electrical Properties, Chemical Properties are also significant with regard to processing.

[Top of Page]

6. Types of Packaging Materials

Norbert Buchner

The relative proportion of various types of packaging material has remained essentially unchanged over a number of years in the Federal Republic of Germany. A significant growth has been recorded only for plastics. In a total manufacturing value of packaging materials amounting to 17×10^9 \$ (1986), paper, cardboard, and corrugated cardboard together account for ca. 40 %, polymers ca. 28 %, metals ca. 22 %, and glass almost 8 % [13]. In the United States, the proportion of paper, cardboard, and metal is higher, and of plastics lower, than in Germany. Accordingly, a considerable increase in the share of plastics is expected [14].

6.1. Paper

Papers are differentiated by:

1. weight per unit area (generally between 20 and 150 g/m^2);
2. type of raw material (sulfate or sulfite cellulose, wood-free or wood-containing, primary fiber or recycled paper);

3. surface (machine-coated, one-side calendered, i.e., postsmoothed, calendered, coated); and
4. special type (simple packing paper, chipboard, natronkraft paper, kraft liner paper, tissue paper, crepe paper, microcrepe paper, wet tensile paper, greaseproof paper).

The proportion of secondary fiber materials (recycled paper) in the Federal Republic of Germany amounts to almost 50 % of all packaging paper.

Paper is suitable for packing foods that do not require much protection, such as sugar and salt. Similarly, paper is used for dried cereal, potatoes and rice products, where water-permeable packaging is necessary so that in the event of a reduction in temperature, and resulting increase in relative humidity, the threshold marking the onset of mold growth is not exceeded (often incorrectly referred to as “breathing packaging”).

The term *special paper* includes silk papers (20 g/m^2) and the relatively greaseproof and aroma-impermeable variations such as artificial parchment (consisting of a cellulose structure that has been compressed by grinding rollers), glassine (in which the surface is subsequently smoothed by calendering), and vegetable parchment (crude paper that has been broken down in sulfuric acid, neutralized, and cleaned). This last type is used frequently for relatively odor- and greaseproof inner pouches or wrappings. In several applications, however, it has been replaced by coated paper.

6.2. Cardboard

Cardboard is a fibrous material which has normally been couched together from numerous layers while still wet. An exception to this is cellulose cardboard, which is manufactured as a monolayer from cellulose fibers. Multilayer cardboard is also available, such as chromo and imitation chromo cardboard (made from primary materials with a wood-free top layer) as well as duplex or triplex cardboard (incorporating a reverse side or an intermediate layer of gray secondary materials). All these types of cardboard are also available with a lacquered surface [15]. The proportion of secondary fibers present in cardboard in the Federal Republic of Germany is approximately 85 %.

Cardboard is used for food-packaging applications similar to those described for paper. In addition, cardboard packets can be subjected to mechanical loads, stacked, or designed to meet advertising requirements as outer casings for pouches, tubes, boxes, etc.

6.3. Corrugated Cardboard

Solid cardboard materials have been replaced in a variety of applications by material-saving corrugated cardboard, which has been developed over the past hundred years [16]. Single-side corrugated cardboard (one layer of corrugated paper with a top layer, usually bleached on one surface) is often employed as a padding or cushioning material in packaging fragile articles, such as pastry and cookies. Singly corrugated cardboard (a single layer of corrugated paper incorporating a top layer on both surfaces) is the typical material used in food packaging to transport packets, trays, and fruit boxes, e.g., where the packets are formed by subjecting the articles to wraparound processes. When heavy articles are involved (e.g., for “bag in box” applications with liquids), multiple corrugated cardboard is employed. The proportion of corrugated cardboard manufactured from secondary fibers is as high as 95 % in the Federal Republic of Germany.

6.4. Coated Paper and Cardboard

Paper and cardboard are coated with waxes to impart water vapor impermeability and render them waterproof. Additionally, heat-sealing properties can be gained by coating with hotmelts (mixtures of waxes and polymers); with polyethylene (see Section Polyethylene) which is watertight in addition to that; and ethylene ionomers (see Section Ethylene Ionomers) which are especially well heat sealable and generate a barrier to fats and aromas. Similarly, coatings based on poly(vinylidene chloride) copolymers (extremely strong barrier properties with respect to odors, fats, and water vapor, along with heat-sealing characteristics), rubber latex (cold-sealing properties), and fluorinated hydrocarbons (grease and fat resistance), are relatively common. Cellulose cardboard coated on both surfaces with polyethylene is employed in large quantities for containers used in packaging milk and other dairy products, as well as products suitable for freezing. The inner polyethylene layer provides the necessary liquid barrier to contain the product, whereas the outer coating ensures the hydrophobic qualities necessary to prevent any problems with condensed water. By additionally incorporating aluminum foil, the aseptic packaging of products such as milk, fruit juice, still beverages, and more recently, tomato concentrate, apple sauce, and soup, has been made possible. Special paper that includes a coating of partially crystalline thermoplastic polyester can be employed for packaging and baking trays suitable for use at oven temperatures of 220 °C. Duplex papers with an intermediate layer of wax, hotmelts, or polyethylene have excellent adhesion properties.

6.5. Plastics for Packaging

The average costs (1988) of different types of plastics used in food packaging are given in the following material.

Plastic	Costs, $/kg
ABS	1.81
Acrylonitrile (barrier plastic with high acrylonitrile content)	1.76
EVOH	5.30
HDPE	0.77
LDPE	0.75
LLDPE	0.77
PA 6	3.53

PA 66	4.19
Amorphous PA	3.75
Oriented PET	1.32
PP	1.04
PVC	0.73
PVDC	2.54
Polycarbonate	4.08
Polystyrene	1.15

6.5.1. *Cellophane (Regenerated Cellulose) (⟶)*

Cellophane [9005-81-6] was originally used for packaging applications in 1924 and coated with a heat-sealing layer for the first time in 1929 (Du Pont). Since about 1970, cellophane has been increasingly replaced by alternative products, particularly heat-sealable, oriented polypropylene film. This development is quite advanced in both the United State and Japan [17], [18]. Because of its adaptability, however, cellophane will remain irreplaceable in certain sectors in the future.

The advantages of cellophane lie in its transparency and gloss, as well as favorable barrier properties toward many aromas and fats. Its inherent brittleness is overcome by hygroscopic, moisture-retaining agents (polyhydric alcohols); the properties, however, remain strongly dependent upon environmental conditions; especially the humidity of the environment. This can be reduced by coating with various, normally heat-sealable, materials [nitrocellulose, vinyl copolymers, poly(vinylidene chloride) copolymers], which improve the barrier properties of cellophane to odors, water vapor, and gases and enable films to be heat-sealed.

This gives one special advantage to cellophane: the base film is not thermoplastic, and the coatings allow heat sealing to be carried out over a wide temperature range. Another advantage is that optimal choice of coating allows barrier properties to be tailored to suit specific requirements. The greatest barrier properties are achieved with poly(vinylidene chloride) (PVDC) lacquers or coatings. Cellophane is also employed as a base film in laminates, where again it is facing strong competition from oriented films based on polyester (O-PET), polyamide (OPA) and polypropylene (OPP).

Applications of coated cellophane products include the packaging of baked goods, snacks, cheese, coffee, candy, and spices. Cellophane is also used as a wrapping to improve appearance.

6.5.2. *Polyethylene (⟶ Polyolefins)*

Based on figures for the 1980s, polyethylene (PE) represents approximately two-thirds of the total usage of plastics in the packaging industry. The various products available are normally broken down according to their density (⟶ , ⟶ ; ⟶ Polyolefins). Polymer properties can be varied by mixing the components.

Alternatively, ethylene can be copolymerized with polar comonomers. The resulting polymers include EVM [24937-78-8] (ethylene – vinyl acetate copolymer), EAA [9010-77-9] (ethylene – acrylic acid copolymer), and EMA [25103-74-6] (ethylene – methacrylic acid copolymer). Apolar comonomers include butene, hexene, octene, and methylpentene which are present in low concentrations in LLDPE (linear low-density polyethylene). By mixing, particularly the homopolymers, a multitude of products is available.

Polyethylene is very inexpensive (see Section Plastics for Packaging), chemically stable, relatively easy to weld, tough with a large strain potential, and insensitive to reduced temperatures. It can be employed over a wide temperature range. Additionally, it is an excellent barrier to water vapor, but only average with regard to the permeability of gases, aromas, and fats. Barrier properties increase with increasing density, as do the degree of crystallinity, strength, stiffness, hardness, and melting temperature. Contrary to this, the toughness, impact strength, transparency, sensitivity to reduced temperature, and resistance to stress cracking decrease with increasing density.

Low-density polyethylene [9002-88-4] (LDPE) is the least expensive product and is used most frequently for films, coatings, and laminating purposes. Linear low-density polyethylene is increasingly employed as a replacement for LDPE because of its increased strength and toughness (which allows a reduction in thickness), the increased temperature range for welding, and the better hot-tack properties. Typical applications include sealing layers in laminates, freezer bags, shoppery bags, sacks for heavy goods, and stretch films.

High-density polyethylene [9002-88-4] (HDPE) is employed for applications where increased impermeability to fats (meat packaging etc.) and aromas, increased stiffness (injection-molded articles such as crates), or increased temperature stability (milk bottles that can withstand sterilization in an autoclave) is important. The special high molecular mass polyethylene (HMPE) is used mainly for small, stiff carrier bags.

Ethylene – vinyl acetate copolymers with vinyl acetate contents below 10 % are also used in packaging applications. Compared to polyethylene homopolymer products, these copolymers show increased strain properties, transparency, stability to reduced temperature, and welding properties (lower melting point). Typical applications include sealing layers in laminates, freezer bags, elastomeric stretch films, and sacks for heavy goods.

Ethylene – acrylic acid copolymers with acrylic acid contents up to 10 % are similarly employed in food-packaging applications. These copolymers can be welded over a wider temperature range than the homopolymer and also show increased hot tack properties (see Section Welding and Heat Sealing of Packaging Materials), strength of welded seams, adhesion to other materials, and resistance to stress cracking.

Ethylene – methacrylic acid copolymer (EMA) has a lower melting temperature as well as improved welding properties and adhesion in laminates. The elongation at break is increased, albeit at reduced strength, and the sensitivity to low temperatures is extended to –76 °C.

Applications. The main applications for homo- and copolymers of ethylene, with a share amounting to ca. 70 %, are associated with films. Extrusion coating and laminating amount to 7 %. Films are used as wrapping, as materials to produce bags and sacks, as shrink and stretch films and as heat-sealing layers in laminates. Many substrates are extrusion coated with PE, e.g., cardboard (see Section Corrugated Cardboard), paper, cellophane, and oriented films based on polyester, polyamide, and polypropylene. During this process, barrier layers can also be included to permit the manufacture of packaging that is impermeable to water vapor, gases or odors, that can be sterilized by using heat, and that can be hot- or aseptically filled (see Section Barrier Polymers).

Coextrusion with similar or dissimilar polymers is continually gaining in importance. With dissimilar polymers, the objective is usually to include reinforcing or barrier materials, whereas with similar polymers, an improvement in processing properties is generally sought. Typical examples include composites of stiff, highly heat-resistant HDPE with the excellent welding LDPE (or, possibly, LLDPE or ethylene copolymers). Similarly, composites with an LLDPE core and surface layers of EVM are common as stretch films with autoadhesion ("cling") properties [19-21].

6.5.3. *Ethylene Ionomers*

Ethylene ionomers are copolymers made from ethylene and acrylic acid, in which the latter is partially present as either the sodium or the zinc salt. The polymer thus contains both covalent and ionic bonds. Ionomers have a major disadvantage compared to polyethylene because they are expensive and can be used only within a narrow temperature range. In contrast, they have the advantage, depending upon variant, of introducing further improvements, such as excellent adhesion to other substrates (useful laminating agents with good delamination resistance), increased hot tack with simultaneous low melting temperatures, (see Section Welding and Heat Sealing of Packaging Materials) (this leads to increated welding speed and safety), improved toughness and perforation strength, as well as favorable fat impermeability.

6.5.4. *Polypropylene (⟶ ; ⟶ Polyolefins)*

Polypropylene [9003-07-0] (PP) films have been available since the beginning of the 1960 s. Like polyethylene, polypropylene is one of the least expensive mass-produced polymers.

As with PE, the water vapor barrier properties of PP are good (lying between those of LDPE and HDPE). However, it has only average impermeability to gases and aromas. Polypropylene acts as a better barrier to fats than LDPE. It also has a much higher melting temperature (165 °C) than PE and can be employed up to ca. 140 °C. When crystallization is hindered by quenching, its transparency is also considerably greater than that of polyethylene.

Standard PP film (homopolymer) is rarely used for packaging purposes because it is only stable down to 0 °C. A typical application is for packaging bread. Copolymers with ethylene are employed to improve the stability to reduced temperature, welding properties (by reducing the melting point), thermal stability, and toughness, particularly of welding seams. Typical applications include injection-molded containers for frozen foods such as ice cream, heat-sealing layers for sterilizable packaging substrates, and steam-sterilizable cups and menu trays that can be sterilized in an autoclave and warmed in a microwave oven. More recent developments include multilayer bottles and cans incorporating a barrier layer that can be hot-filled or sterilized in an autoclave.

The *orientation* of polypropylene, mostly biaxial, (⟶), improves its mechanical strength, impermeability, transparency, and stability to reduced temperature (to –50 °C); it also permits shrinkage. *Monoaxial orientation* is employed particularly for tapes (straps, tapes for woven sacks). Uncoated *biaxially oriented* PP film (OPP) is an inexpensive base film for laminates.

Coextruded OPP films have taken a major step in replacing two-sided heat-sealable, coated OPP film (e.g., with PVDC, to increase barrier properties to gases and aromas) and cellophane. The coextruded fims, with surface layers between 2 and 3 µm thick, consist of copolymers with ethylene or terpolymers. The outstanding properties include high transparency, stiffness, strength, and—given the limited temperature loadability—good processing characteristics [22], [23].

6.5.5. *Poly(Vinyl Chloride) (⟶ ; ⟶ Poly(Vinyl Chloride))*

Poly(Vinyl chloride) [9002-86-2] (PVC) is a material with very well-balanced properties; its costs are in the medium range; it offers a relatively good barrier to gases, aromas, and fats; and frequently, it alone is sufficiently impermeable to water vapor. Additionally, PVC is highly transparent and glossy, has adequate strength and stiffness, and has excellent thermoforming properties with a wide thermoelastic range (80 –150 °C). Whereas several PVC products soften as low as 60 °C or 70 – 75 °C, modifications also exist that can be hot-filled at 80 – 85 °C (e.g., blends with chlorinated PE).

Films of PVC are manufactured mainly in a calender process, but they can also be produced by extrusion. The advantage of PVC films lies in their high elastic strain and high oxygen permeability, which retains the desired red coloration of oxymyoglobin in packaged meat .

Other major applications are the thermoforming of containers and trays for cooking oil, baked goods, and snack articles; sorting trays for chocolates; and the manufacture of corresponding heat-sealed coated lids. In several cases, replacement by PP has already begun. Biaxial orientation, improves the impermeability and strength of PVC. Such films can be employed as decorative shrink-wrapped films [24], [25].

Bottles made of PVC—also biaxially oriented—are used particularly for mineral water and cooking oils. Here, replacement by polyester is underway.

The use of poly(vinyl chloride) has been criticized on several occasions because it is manufactured from carcinogenic

monomers and because of its combustion products, which include chlorine gas and, if water is present, hydrochloric acid. Additionally, PVC is suspected of contributing to the formation of dioxins. The use of stretch films containing plasticizers, to package fresh meat and fruit in trays, is disputed as well. In this case, to minimize the transfer of materials present in the film, approved film thickness and applications have been regulated. Direct contact with foods of high fat content is to be avoided [26].

To pose no health hazard, the content of vinyl chloride monomer should be limited to less than 10 ppb in foods and 1 ppm in PVC. In incinerators, ca. 50 % of the chlorine content is originated from PVC; the exhaust gas washing stages (which are employed during the incineration of all materials) capture the hydrochloric acid. Combustion trials involving excess amounts of PVC have proved that dioxin is not formed during correct incineration. More recent investigations carried out in the Kernforschungszentrum in Karlsruhe (Federal Republic of Germany) have suggested that dioxin formation can be attributed to inorganic chlorine compounds.

6.5.6. *Polystyrene and Styrene Copolymers (⟶ Polystyrene and Styrene Copolymers)*

The following styrene polymers and copolymers are used for packaging purposes:

1. standard polystyrene (PS),
2. styrene – butadiene copolymer (SB, impact-modified polystyrene),
3. styrene – acrylonitrile copolymer (SAN), and
4. acrylonitrile – butadiene – styrene copolymer (ABS elastomer, modified SAN).

Additional variations and blends are available.

Standard Polystyrene. The advantage of PS [9003-53-6] lies in its great stiffness combined with average cost, along with favorable processing properties during injection molding and thermoforming (110 – 160 °C). A disadvantage is its high permeability to gases and vapor. Hence, polystyrene is typically employed as a packaging substrate for the short-term storage of relatively insensitive products, often under refrigerated conditions, e.g., dairy products that do not have a high fat content (yogurt, cottage cheese, ice cream, cream). Polystyrene is also used in sorting trays for fruit, eggs, baked goods and candy. Standard polystyrene is highly transparent and stiff, although it is also brittle and prone to stress cracking. Biaxially oriented products are employed within limits. Copolymers can be hot-filled up to approximately 80 °C.

Styrene – Butadiene Copolymers. Depending on the butadiene content, the stiffness, and transparency of SB copolymers [9003-55-8] decrease while impact toughness increases. A block copolymer with a fine distribution of the polystyrene or polybutadiene phase is crystal clear. The complex manufacturing process required leads to high costs. Styrene – butadiene copolymers are used as materials for cups and containers for the packaging of dairy products.

Styrene – Acrylonitrile Copolymers. Relative to standard PS, several properties of SAN copolymers [9003-54-7] are improved, including stability to oils and aroma substances, the upper limit of application temperature range, and gas barrier properties. An increased acrylonitrile content makes the polymer a suitable barrier toward gases.

Acrylonitrile – Butadiene – Styrene Copolymer. The ABS copolymer [9003-56-9] has high impact strength but is not transparent. Thermoforming properties, stability towards fats, impact toughness, and stability to reduced temperature (as low as –40 °C) are all favorable. Because of its high cost, the polymer has limited use as a packaging substrate, e.g., as a component in coextruded multilayer films [27-30].

Polystyrene and styrene copolymers with PE as an inner barrier for steam, along with additional barrier and tie layers, are coextruded to a thermoformable composite film possessing excellent impermeability to water vapor, gases, and odors. Such composites are increasingly employed for the manufacture of single-portion containers under aseptic conditions (e.g., for desserts) and permit a storage time up to one year at room temperature.

6.5.7. *Thermoplastic Polyesters (⟶ ; ⟶ Polyesters)*

The term thermoplastic polyesters refers to a group of high-quality polymers of which poly(ethylene terephthalate) [25038-59-9] (PET or PETP) is the most significant. Additionally, poly(butylene terephthalate) [24968-12-5] (PBT) and glycol-modified PET (PETG) are also important in packaging.

Properties. At present poly(ethylene terephthalate) occupies the mid- to high-price range, although the long-term trend is toward lower prices due to increased application. Films made of PET represent an average to good barrier to gases, aromas, and fats, and possess adequate to good impermeability to water vapor. Poly(ethylene terephthalate) is a high-strength material that can be employed over a wide range of temperatures (–60 to 200 °C in short-term loading, e.g., during heat sealing). Poly(ethylene terephthalate) is partially crystalline; its strength and temperature stability increase with increasing crystallinity. A disadvantage of polyesters is the relatively low glass transition temperature (PET: 73 – 79 °C; PBT: 36 – 49 °C), which means that in a highly amorphous condition, the materials are unsuitable for applications involving hot filling. This property can be obtained however by crystallization at elevated temperature in a forming mold (PBT crystallizes more rapidly), as well as by blending or coextruding with a material of higher thermal stability.

Areas of Application. Thermoformable, unoriented films are available, including a heat-seal layer when required, but these materials do not play a significant role in packaging. Tubular polyester films are used as baking films.

Biaxially oriented PET films (⟶ Films – Polyester) account for a very important range of products. Orientation improves transparency, strength, and impermeability. High short-term thermal loadability has resulted in O-PET film (most frequently, 12 µm thick) becoming one of the most important base films for the manufacture of impermeable, flexible composites, for use over a wide temperature range. Because long-term thermal loadability is guaranteed to >150 °C, these can also be employed as base films in the production of composites capable of being sterilized in an autoclave.

Polyesters find further application as baking trays for hot-air ovens at temperatures ranging from 200 to 220 °C. Such articles are manufactured from crystallizable PET or from special cardboard that has been coated with PBT.

The utilization of biaxially oriented bottles, wide-neck containers, and cans made from polyester is increasing. Bottles for sparkling beverages were developed at the beginning of the 1970 s, particularly for 1.5- and 2-L sizes, because of the weight problem and danger associated with breakage of equivalent glass containers. Meanwhile, PET is used for bottles of other sizes to contain commodities such as water, cooking oil, and alcoholic beverages. For packaging beer and wine, improvement of gas barrier properties is necessary. This can be attained by a PVDC coating on the outer surface or by coextruding a barrier layer of amorphous polyamide [31-34].

6.5.8. *Polyamides (⟶ ; ⟶ Polyamides)*

From the approximately 20 different polyamide (PA) products presently available, the most important in terms of packaging are PA 6 [25038-54-4], PA 12 [24937-16-4], PA 6/66 [32131-17-2], PA 6/12, and PA 11 [25035-04-5] (numbers correspond to the number of carbon atoms between NH groups). While PA is partially crystalline, PA 6/66 and PA 6/12 have the lowest degree of crystallinity. An increase in the degree of crystallinity increases stiffness and impermeability but reduces transparency.

Properties. Polyamides are high-quality polymers in the mid- to high-price range. Depending on the degree of crystallinity, they vary from highly to relatively transparent; they have high strength and toughness, average hardness and stiffness, and are relatively impermeable to gases, aromas, and fats. Because of their hydrophilic character, polyamides constitute only an average barrier to water vapor. Melting point varies, according to product, from 175 to 255 °C; stability to low temperature varies from –50 to –70 °C.

Applications. Polyamides, as monofilms, are of little importance because the rapid transition to a low-viscosity melt during welding hinders processing. Tubes made from PA 12, or coextruded from PA 6 and PA 12, are used for frankfurter-type sausages. The primary use of polyamides is in the manufacture of laminates, particularly in combination with polyolefins (PE, ethylene copolymers, PP) which complement the properties of PA with favorable water barrier and welding characteristics. Combinations with unoriented PA, including additional barrier layers, are often employed as thermoformable laminates in tray-type packaging (under vacuum or incorporating a protective gas) for meat products, fish, and cheese.

Biaxial orientation leads to improvements in impermeability, strength, stiffness, and transparency. Oriented polyamide films are important base materials for laminates incorporating a heat-seal layer and, possibly, further barrier layers. Such laminates are used in vacuum and protective gas packaging for coffee, powdered milk, meat products, etc. Another application is as the inner bag in “bag in box” system for liquids [33], [35].

6.5.9. *Polycarbonates (⟶ ; ⟶ Polycarbonates)*

Polycarbonates (PC) [25037-45-0] are relatively expensive and, because they are amorphous, crystal clear. They are stable as low as –90 °C and as high as 135 °C (for sterilizing); however, they are permeable to gas and water vapor. Investigations are underway to determine the possible use of PC for hollow packaging, in combination either with barrier layers or with thermally sensitive structures to increase the heat stability in applications involving pasteurization or heat sterilization.

6.5.10. *Barrier Polymers*

Barrier polymers are highly impermeable to gases and usually also to flavors [36-40]. This field is developing rapidly because in some cases, barrier polymers can partially replace glass and sheet metal. Examples are poly(vinylidene chloride) copolymer, poly(vinyl alcohol) (PVAL) ethylene – vinyl alcohol copolymer, high-barrier polyamide, and polyacrylonitrile (PAN) blends with high acrylonitrile content. Products from poly(amide – imide) are also being developed. Figure 1 shows oxygen permeability ranges for some of these plastics.

Figure 1. Oxygen permeability range of barrier polymer membranes at 30 °C (membrane thickness = 25 µm)

Poly(Vinylidene Chloride) Copolymers (⟶ ; ⟶). Copolymers of PVDC [9002-85-1] were the first barrier polymers. They are partially crystalline thermoplastics with a composition of at least 50 wt % vinylidene chloride (VDC), copolymerized with other comonomers such as vinyl chloride (VC), acrylic acid methyl ester (methyl acrylate), methacrylic acid methyl ester (methyl methacrylate), acrylonitrile (AN), and unsaturated carboxylic acids. They are employed as aqueous dispersions, lacquers, or extrudable granulates. The melting point of pure PVDC lies above its decomposition temperature; therefore, comonomers must be copolymerized into extrudable systems to bring about a reduction in melting temperature. In these cases, the content of VDC is ca. 75 – 90 %. In dispersions and lacquers, it can reach 94 %. Barrier properties increase with increasing VDC content.

The advantage of PVDC is the extremely low permeability of gases, water vapor, aromas, and fats under dry and moist conditions. Particularly high barrier properties are possible with more recent products that include AN as a comonomer. Disadvantages include the relatively difficult processing characteristics, the chlorine content, and associated problems in recycling production scrap with mixed polymers. Poly(vinylidene chloride) copolymer dispersions are used to coat paper, cardboard, cellophane, OPP, PET, and PA films, and to improve the barrier properties of PET bottles. Lacquers can be similarly employed as heat-sealable barrier coatings on such films. The plastic is extruded to form monofilms and barrier layers in flexible films, as well as thick thermoformable composites.

Poly(Vinyl Alcohol) and Ethylene– Vinyl Alcohol Copolymers (⟶ , ⟶ ; ⟶ Polyvinyl Compounds, Others). In ethylene – vinylalcohol (EVOH) [25067-34-9] copolymers, the moisture sensitivity of poly(vinyl alcohol) (PVAL) [9002-89-5] is reduced by copolymerization with ethylene. The vinyl alcohol content ranges from 66 to 82 %. A variety of specialty products are available which can be processed be extrusion techniques, e.g., with increased barrier properties, improved thermoformability, and greater resistance to fracture on bending.

Depending upon the ethylene content, which generally lowers barrier properties, EVOH copolymers have far superior gas impermeability than PVDC determined under dry conditions. A disadvantage for use in humid conditions or in packaging aqueous liquids is that EVOH is strongly hygroscopic, and water uptake causes a drastic increase in permeability. The extrudability and recyclability of mixed production scraps are an advantage.

Ethylene – vinyl alcohol copolymer is present in coextruded flexible, high-barrier composite films (e.g., PA – EVOH – PE) and also in thick thermoformable structures for containers and trays, which can be heat-sterilized and are suitable for use in microwave ovens. It is also employed as a barrier layer in multilayer bottles. For packaging moist articles, a water vapor barrier layer (thick polyolefin) is selected for the inner surface, along with an outer surface of a less impermeable material (a layer permeable to water vapor or a thin PP layer) to keep the EVOH as dry as possible.

Amorphous Amorphous Polyamides (⟶ Polyamides). A new group of materials still in the development stage and not yet approved for applications involving foodstuffs, the new amorphous polyamides have all the advantages of PA 6 but also are highly transparent and have favorable stiffness properties at high humidity levels. They can be processed by injection molding, extrusion, blow molding, and thermoforming techniques because a well-defined crystalline melting point is no longer present. Relative to partially crystalline PA materials, the gas, water vapor, and aroma barrier properties are increased, while gas permeability under humid conditions decreases slightly. Because of their high dimensional stability at elevated temperature, amorphous polyamides are particularly suitable for applications involving hot filling or heat sterilization. Current development is directed toward applications involving films and uni- or multilayer containers. In the last case, amorphous PA would govern the barrier properties and also improve the high-temperature dimensional stability. In Japan, wine bottles have been manufactured which consist of a PET – amorphous PA – PET structure.

Poly(Acrylonitrile) Multicomponent Blends. At the beginning of the 1970 s, a range of blends with high AN content (e.g., 70 – 95 %) were developed with properties including gas impermeability, transparency, high strength and stiffness, favorable processing characteristics (injection molding, extrusion, blow molding, thermoforming), and thermal stability up to 90 °C. Areas of applications involved the packaging of fruit juices, alcohol, beer, cooking fat, and sauces. These materials are accepted by the European authorities. In 1977, the U.S. Food and Drug Administration (FDA) banned the material because of possible health hazard due to the migration of AN monomer. Since 1984, however, PAN has been accepted in the United States, albeit with defined limits relative to the monomer components (1 ppm).

A recent blend of PET and EVOH from Japan can also be included in a list of barrier materials. This may mark the onset of a new developmental route: generating barriers not by clearly defined individual layers but by integration into a single layer. Processing will undoubtedly be simplified by this trend.

6.5.11. *Foamed Plastics (* ⟶ Foamed Plastics*)*

The foaming of polystyrene (expanded polystyrene, EPS) can be attributed to developments at BASF in 1951. Expanded polystyrene films are used in thermally insulating drinking cups, trays for fresh meat, and packaging for dairy products. They are also employed as padding materials in the form of boxes, matrices, inserts, and inert filler chips [41-43]. Like EPS, foamed PE films are also important for padding.

6.5.12. *Polymer Composites*

In many applications, a monofilm cannot meet the demands made of packaging substrates. Hence, to reach a desired property profile, several materials are combined. This can be achieved by:

1. introducing additional layers onto base film by coating with lacquers, melts (polymers, hot-melts), or dispersions;
2. laminating of webs which have been manufactured previously (pastes, lacquers, reactive adhesives, polymer melts, hotmelts, waxes); or
3. coextruding different polymers. The last leads to increased process economy (utilization of expensive components as thinner layers, incorporation of reclaimed material) and savings in subsequent processing (see Sections Polyethylene), as well as improved thermal behavior (see Section Thermoplastic Polyesters) and barrier properties (see Section Barrier Polymers) [44]. At present, thick thermoformable composites are manufactured via coextrusion with up to six separate layers and a maximum width of 1.8 m.

6.5.13. *Aluminum-Polymer Laminates*

Today, aluminum foil for packaging applications can be rolled to thicknesses as low as 7 µm. Besides the discontinuous rolling of blocks, a continuous process involving casting and rolling is used. Typical foil thicknesses lie between 7 and 15 µm. Depending upon the alloy, freedom from pinholes is possible at thicknesses greater than 15 – 18 µm. After being rolled, most foils are annealed at ca. 400 °C. The extension at break, which is only 2 – 3 % with thinner foils, increases with increasing thickness to a value of 25 – 30 %.

Aluminum foil that is merely coated with a protective lacquer is rarely used for other than decorative applications (wrapping for chocolate, candy, cheese). After being coated with sealing layers, foils can also be employed as film lids for cups. In the absence of pinholes, aluminum foils are impermeable to gas, vapor, aromas, liquid, fat, visible light, and UV or IR radiation. Coatings and polymers cover any pinholes so that with suitable aluminum – polymer composites, extraordinarily high barrier properties can be obtained. If adhesive layers are ignored, high-barrier laminates often have a three-layer structure. The outer surface consists of the mechanically strong base film made of O-PET, and OPA OPP, or cellulose. The aluminum foil is in the middle, and the inner surface represents the heat-sealing layer (usually PE, ethylene copolymers, or PP). With correct

property matching between the aluminum and polymer films, as well as high-quality laminating, the danger of failure at the grain boundaries of the aluminum crystallites caused by mechanical loading is reduced. In fact, the crystallites may be elongated. Shallow containers, which can be sterilized at 121 °C, are manufactured by drawing such laminates (see Section Thermoforming of Polymers). These are used along with semirigid trays made of aluminum from 70 – 150 µm thick (with a heat-sealing layer), which are manufactured similarly by using thermoforming techniques [45], [46].

Aluminum tubes are manufactured by compression. The inner surface is lacquered with a material that prevents contact with the food; the outer surface is printed and lacquered. Their advantage over polymer tubes results from the fact that aluminum tubes are gastight and free of any recoil effects; this means that after the product is removed from the tube, air is not drawn into the free volume. Such tubes are used to pack mustard, mayonnaise, and tomato concentrate. An interesting variation is in tubes made of a high-quality printed PE – Al – PE laminate; this is wound in a parallel manner and sealed on the longitudinal overlap seam, so that the aluminum cut face on the inner surface is protected by PE that is squeezed out of the seal. The body of the tube is normally equipped with a PE shoulder piece and sealed with a screw cap.

6.5.14. *Metallized Polymers*

Metal evaporation onto paper and PET films in a high vacuum was originally employed with wound capacitors. This discontinuous process has been transferred to packaging materials such as paper and films (O-PET, OPA, OPP, PC, PVC, and cellophane). The layer thickness is generally less than 0.1 µm. The attainable barrier properties (e.g., toward gases) depend not only on the thickness of the layer but also on the morphology and, consequently, on deposition conditions.

Packaging substrates with vacuum-deposited aluminum layers are used for decorative purposes (packaging for candy, bottle labels, sorting trays for chocolates), and also as the barrier layer in laminate structures having relatively high gas impermeability (e.g., for roasted coffee and snack such as nuts, potato chips, or crackers). The barrier properties of laminates incorporating aluminum foil are not achieved; However, the films are often less prone to damage caused by flex cracking.

6.5.15. *Polyester Films with Vacuum-Deposited Silicon Dioxide*

Vacuum deposition of silicon dioxide onto PET films, which was developed in Japan, provides high gas barrier properties equivalent to those of EVOH measured under dry conditions. In contrast to EVOH, however, the permeability does not increase with increasing humidity.

6.6. Metal Cans

Initially, cans were made in three parts, from tin-plated steel; the longitudinal seam was folded and soldered with tin solder (containing lead), which was normally coated with an epoxy or an acrylic resin. Today, this sector has become considerably more diversified: sheet steel is increasingly being manufactured by casting into continuous bars and rolling out to a minimum thickness of 0.14 mm. Electrolytic tin plating has displaced annealing methods, which allows savings of tin amounting to approximately 80 %. The thickness of tin, which often varies according to whether the inner or outer surface is being prepared, is between 2.8 and 11.2 g/m^2. Apart from tin-plated sheet steel, tin-free steel (TFS), meaning sheet steel with a surface of chromium – chromium oxide, is being used increasingly for food packaging. Cans with welded longitudinal seams, as well as two-part cans (either singly or doubly drawn, or, alternatively, drawn and ironed to a minimal thickness of 0.09 mm) have been introduced.

Apart from the precoating of sheet-metal webs, the coating of finished cans—either completely or only in the seam area—is widespread. For reasons of environmental conservation, lacquers containing organic solvents are supplemented by coating compositions in which the solvent has been either partially or fully replaced by water. Additionally, reactive systems have been developed, which are cured by using UV or electron-beam techniques, along with powder coatings that are applied electrostatically and subsequently fused.

Cans made from aluminum sheet play a major role in the manufacture of shallow containers, for example, for packing fish and sensitive meat products. Beverage cans are manufactured from aluminum as well as iron-based metals. A number of products exist which represent alternatives to tin cans. For packaging dried products, combination cans with cardboard as a structural element in the casing and barrier layers made from aluminum foil or plastic can be used. The casing is wound in either a parallel or a spiral configuration, and metal lids are normally attached by rolling. Cans made from plastics (e.g., PP) are also available.

For packaging fruit juices, special composite cans exist in which the casing and the lid are heat-sealed; the cans are filled either while still hot or under aseptic conditions (see Section Aseptic Packaging). The walls of these composite cans are made of PE – cardboard – PE – Al – PE (starting from the outside layer, the lids consist of PVC – Al – PE, or cardboard – PE – Al – PE). For sparkling drinks, two- and three-part cans have been developed with a body or casing made from PET with rolled-on metal lids.

For sterilized products, a two-part can has been developed in the United States, with a body made of PP – EVOH – PP composite and a rolled-on metal lid. Apart from this, a newer can manufactured in Sweden is available in which the body and both end pieces are made from PP – Al – PP. Further competitors include sterilizable trays made from PP that incorporates intermediate polymeric barrier layers, as well as aluminum foil coated with PP [47-50].

6.7. Glass Bottles and Wide-Neck Containers

Blown-glass bottles for beverages, salad oil, sauces, and vinegar have been manufactured since about the middle of the 19th century. In the past two decades, careful analysis of this process, optimization of conditions, and willingness to accept certain compromises in the shape of the bottle (partly to promote standardization and interchangeability) have made possible a weight reduction of up to 50 %.

The press-blow process permits the manufacture of lighter narrow-neck bottles with relatively constant wall thickness and in

the production of wide-neck containers, weight reductions greater than 50 % are possible.

The surface of the bottles is modified to avoid their premature fracture due to notch effects caused by the presence of microcracks in the surface. During the hot end-treatment, the outer surface is coated with tin chloride or titanium chloride which reacts with glass and hardens between 500 and 600 °C. In the subsequent, final, cold end-treatment, which is essentially intended to increase frictional properties, aqueous solvents or dispersions of organic materials (e.g., waxes and plastics) are sprayed onto the bottles at temperatures between 80 and 150 °C. Because material transport to the inner surface cannot be excluded, these materials must conform to Recommendation XLVIII of the Health Administration of the Federal Republic of Germany (BGA). Bottles with shrinkable sleeves made from polystyrene foam or shrinkable labels made from PVC film, along with other polymer coatings applied by immersion techniques, are available to meet the following requirements: labeling, decoration, noise insulation, protection against shattering, or prevention of surface damage.

Because glass bottles are completely airtight, gas permeation is possible only through the cap or, when metal caps are involved, through the seal that is pressed against the mouth of the bottle. This seal is usually made from plasticized PVC or PE. For crown corks, screw caps, and vacuum lids, minimum oxygen transmission rates of 0.004 cm^3/d (23 °C) have been reported [51]. Due to the danger of tampering, caps incorporating safety devices, such as tear-off or break-off rings, are being employed increasingly or even stipulated in some countries for certain applications.

Wide-neck glass containers for preserved foods, marinades, salads, and instant powders are manufactured according to the optimized press-blow process. Screw cap, twist-off, and press-on lids made from metal, with polymeric seals, are employed as lids. For packaging dry products, that are sensitive to water vapor, plastic screws and spring caps, including sealing membranes which are glued or heat-sealed to the lip of the glass, are also used.

Great effort has been made to seal wide-neck containers by using plastic-coated aluminum membranes. Pretreatment of the container surface in the vicinity of the mouth is a prerequisite if the seal on the hydrophilic glass surface is to be stable to liquids. Sealing equipment must be able to take into account any irregularity of the glass surface [52].

Bottles and wide-neck containers made from glass are being replaced by plastics. Bottles made from PVC for salad oil, vinegar, and mineral water, as well as sterilizable bottles made from HDPE for milk, have been used since the beginning of the 1960s. Since 1975, carbonated beverages are also available in PET bottles, either with or without an outer PVDC coating. Newer developments include gastight bottles with barrier layers made from EVOH or amorphous PA within a structure of sterilizable PP or PET (see Section Barrier Polymers) [53], [54].

[Top of Page]

7. Packaging Machines

Horst Weisser and Heinrich Vogelpohl

According to DIN 8741 Part 1, *packaging machines* are those machines which carry out either completely or partially the processes involved in packaging (e.g., forming, erecting, filling, sealing, and wrapping), as well as those processes prior or subsequent to the actual packaging steps which nevertheless contribute in some way to the manufacture of packages ready for distribution, storage, and retail [55]. Machines which are involved only in the manufacture of packaging materials or packaging accessories, and do not form an integral part of a packing line (e.g., machines to manufacture bottles, cans, tubes, folded boxes, etc.), do not constitute packaging machines.

A breakdown of packaging machines according to the technology involved is shown in Figure 2.

Figure 2. Breakdown of packaging machines

Normally, a packaging machine completes many sequential functions. A typical multifunctional packaging machine can, for example, form a tubular packaging substrate from a film material wound on a roll, fill this with the product, and then generate a filled tube by sealing in the transverse direction before cutting to produce individual bags or pouches. The individual tubular pouches can subsequently be packed in folded boxes which, in turn, are collected in containers for transportation. The term *packaging line* is applied to such a system [55]. A packaging line can also include machines that are not themselves packaging machines, e.g., closing and sealing units or weight control aggregates.

Whereas general packaging technology represents an extremely comprehensive area ranging from the packaging of tablets to packing bulk containers, food-packaging technology is limited to so-called retail packaging. According to DIN 55 405, Part 5, this is described as packaging in which the design is governed by the requirements imposed during the distribution of the goods and the selling to the final consumer [56]. As a rule, food packaging deals with complete packaging, meaning packaging that has been stipulated by law, involving certain commodities and certain capacities, which is closed and sealed in the absence of the final consumer. The contents of the commodity incorporated in the complete packaging cannot be altered without opening or noticeably tampering with the packaging.

7.1. Unit Operations in Packaging Machines

A special characteristic of many fully automatic packaging machines is the discontinuous mechanism. Within one machine

cycle, the packaging substrate must be formed, filled, and closed. Theoretical studies have been published regarding the movement in drives during a discontinuous operation in machines typically employed in the packaging industry [57]. Complex mechanical processes often take place in packaging machines; on the other hand, the machines are designed in many cases for processing highly specialized packages or products. Therefore, the mechanical functions should be classified logically in terms of unit operations. If a vertical tubular bag machine is used as an example, these unit operations can be described as follows (Figure 3):

1. Unwinding the packaging substrate from a roll.
2. Generating a constant web tension by means of a dancing roller system.
3. Forming the flat packaging substrate into a tube by using a forming shoulder.
4. Sealing the packaging substrate in the longitudinal and transverse directions.
5. Removing the tube with the aid of grips or conveyor belts, depending on the dimensions of the bag.
6. Dispensing the products to be filled into the tube of packaging material either gravimetrically or volumetrically.
7. Sealing the filled tube.
8. Separating the packing into individual bags by means of a guillotine.

Figure 3. Vertical tubular-bag machine

a) Charging pipe; b) Deflector roller; c) Forming shoulder; d) Longitudinal sealing jaw; e) Conveyor belt; f) Transversal sealing jaw; g) Cross-cutter

The routines associated with all packaging machines can be broken down similarly into individual steps. During various stages, the machines come in contact with the packaging material as well as the contents. In most cases, these interactions are of a mechanical nature. Partially the operations are carried out pneumatically or hydraulically.

During these unit operations, many disturbances can occur. For example, with some packaging materials [e.g., cellophane (see Section Cellophane (Regenerated Cellulose)) or cardboard (see Section Cardboard)], mechanical properties vary with the environmental humidity. In these cases, the processing stages of the machine must be adapted to meet processing conditions. During the processing of plastic films, electrostatic effects often appear as unpredictable disturbances. These effects hinder not only the packaging process but, in many cases, filling the packaging as well. Particularly difficult products include ground coffee and polished rice.

7.1.1. *Overwrapping Articles*

The term *overwrapping* refers to a packaging process in which articles of a given shape are wrapped by using a thin planar packaging material and the shape of the article determines the shape of the package itself. In contrast to other forms of packaging overwrapping utilizes almost without exception two-sided, heat-sealable films, preferably films of coated cellophane, polyethylene (see Section Polyethylene), biaxially oriented polypropylene (see Section Polypropylene), poly(vinyl chloride), and cellophane laminates (Section Aluminum-Polymer Laminates). The packaging materials employed must possess a high degree of stiffness, must have a low tendency to revert to the original shape, and must be sealable in short sealing times. A special case of overwrapping is twist overwrapping which is employed mainly by the confectionery industry for packing candy. The packaging materials used need not be sealable; however, they must have good twisting properties and low propensity to untwist.

The most important unit operations and the possibilities of varying them to obtain a smoothly running machine are described in [58]. Here, unit operations including unwinding the packaging material, adjustment of web tension, packaging material takeoff, cutting, forming, and heat sealing are described. Because the properties of the packaging material are essentially fixed and can be influenced to only a small extent by the processing stages in the machine, mechanical processing techniques must by optimally adapted to the packaging material being used.

7.1.2. *Welding and Heat Sealing of Packaging Materials*

The term *welding* is used to describe the bonding of thermoplastic packaging materials by means of heat, either with or without pressure. In contrast, *heat sealing* is used when only the thermoplastic surface layers of the base materials are bonded under the influence of temperature and pressure. The base materials themselves are not plasticized.

A knowledge of the sealing properties of packaging materials is of major importance in the packaging industry. The welded seams should be airtight and strong, and ideally should form within a fraction of a second. The necessary melting energy is provided either by heating or by using ultrasonic techniques. With heated contact processes, the energy is transferred from heated sealing jaws (see Fig. 4) via the external layers and the bulk of the packaging material to the actual sealing layers on the inner surfaces of the substrate. With ultrasonic techniques, the melting energy is introduced by using a high-frequency horn; the necessary heat is generated by the intrinsic friction.

Figure 4. Cross section of a permanently heated sealing jaw

a) Jaw; b) Cutter; c) Cartridge heaters; d) Thermoelement; e) Channels for cooling air; f) Teflon coating; g) Top ejector

The actual sealing time, sealing pressure, and sealing temperature or, in the case of ultrasonic sealing, the intensity of the high-frequency signal are determined by the construction and adjustment of the machine. In addition, the material and the surface finish of the jaws are important. The quality of the seal is judged by the tensile strength, the hot tack (i.e., the tensile strength measured immediately after the sealing process), the degree of air tightness of the seal, and the optical impressions. The hot-tack values are greater with ultrasonic sealing than with heated contact techniques [58]; as far as the tensile strength of the cooled seal is concerned, the sequence is reversed. Operation at optimum sealing pressure is considerably more important with ultrasonic than with heated contact techniques.

To obtain high production rates, the sealing times must be reduced. With heated contact processes, this is achieved by increasing the sealing temperature; however, this is possible only within the limits imposed by the thermal stability of the packaging material. According to theoretical and experimental analysis, damage to seals is induced at excessive sealing temperatures by the generation of bubbles, discoloration, and creases. The packaging substrate may also adhere to the surface of the welding jaws [59]: Simultaneous increase in sealing temperature and decrease in sealing time lead to a reduction in the seal strength of most packaging materials. If extremely low sealing times (0.05 s) are combined with increased temperature, the seal strength must be expected to be dependent on sealing pressure.

Hot-Tack Properties. The term *hot tack* refers to the strength, and hence the loadability, of the joint while it is still warm, immediately after the sealing jaws are released. All heat-sealing and bonding processes are based on the same principle: the heat-seal layers (or, similarly, hotmelt adhesive) are compressed in a melted condition, causing the substrate to fuse and form a single homogeneous layer. The initial adhesion in the melt viscous state is very low; hence, bond damage is likely to be induced during sealing if the seal is loaded immediately after release of the heat-sealing jaws. Such loading can be caused by adhesion of the packaging material to the sealing jaws, by the weight of the product during the filling of tubular pouches, or even by the mechanical resistance of the packaging material itself (e.g., in wrapping machines). The damage results in either a partial opening of the bond or even an immediate failure of the seal. Latent seal damage can be recognized in the cooled seal by the reduction in bond strength or by leakage at the seams. Latent damage leads to subsequent separation of the seal and, hence, failure of the packaging.

The hot-tack behavior of a seal is influenced not only by the properties of the packaging material but also by the actual sealing conditions. Accordingly, hot tack can also be defined as the cohesive and adhesive strength of a thermoplastic material in the temperature region of the heat-sealing process. The various methods described to measure hot tack can be divided into those that monitor the force required to cause separation and those that measure the separation itself [60]. Data from different tests cannot be compared directly, and no standardized test procedure has yet been described.

7.1.3. *Cold-Sealing Packaging Materials*

According to DIN 55 405, Part 6, cold sealing or pressure-sensitive adhesion describes the bonding of substrates, typically packaging materials, whose surfaces are either completely or partially coated with an adhesive that causes bonding only after the two layers have been compressed [61]. Cold-sealing techniques were applied to food packaging in the early 1970 s, after the development of adhesives that were both suitable for machine processing and approved for use with foodstuffs. In terms of processing, the technology that had been employed in heat-sealing applications was utilized; the temperature of the sealing jaws was simply reduced, or the heat was switched off. The relationships between the effects of processing parameters (sealing pressure, temperature, time and jaw design) and the influence of adhesive composition, base material, and storage conditions on the quality of the seal are only partially known to date.

The starting material for all cold-seal adhesives is natural rubber latex. To coat packaging materials intended for use with foods, a modified latex together with other polymer dispersions is employed. Furthermore, protective colloids which increase the stability to heat, oxygen, light, and mechanical stress are added. The mechanism of adhesion of a cold-seal material can be explained by the freedom of movement of the linear molecular chains in the surface of the cold-seal layer: under the influence of jaw pressure, these become entangled with chains in the opposing surface and thus form a bond.

Investigation into the relationship between seal strength and mechanical or processing conditions has shown that seal strength increases with increasing sealing temperature and pressure [62]. Similarly, seal strength is a function of the thickness of the applied adhesive. The surface profile of the sealing jaws is particularly important; smooth surfaces are undesirable. An improvement in seal strength can be obtained by increasing the sealing time.

7.1.4. *Cutting Packaging Materials*

After the incoming web of packaging materials is unwound from a roll, the cross-cutter stations (see Fig. 5) of the packaging machine cut it into the individual sections required to manufacture the final packaging. The wear mechanisms that occur in the packaging machine during cutting must be known if slitting processes are to be reliably controlled. Shear cutting of packaging films by using straight blades (“open-drawing – intersecting cutting”), according to DIN 8588, has proved to be particularly important in packaging machines [63]. In investigating blade wear in such cross-cutters, the packaging material was found not to lead to blade wear but, in fact, to exert a wear-inhibiting effect [64]. Optimal blade service life can be achieved only by correct adjustment of machine parameters, angle of mesh, dihedral angle, and cutting pressure. An

oscillating relative movement between web and blade during the intervals separating the individual cuts is especially important for long blade service life.

Figure 5. The two knives of a cross-cutter station

a) Revolving knife; b) Bed knife; c) Packaging material

7.1.5. *Web Tension in Packaging Materials*

The machinability of flexible packaging materials is strongly influenced by the web tension on the line. This is particularly true during the forming, filling, and sealing stages of processing machines for tubular bags. In such machines, the packaging material experiences high mechanical stress as it is drawn over the forming shoulder. The takeoff forces that are generated can be considered a measure of the processing quality. Material properties including *bending stiffness, dynamic coefficient of friction,* and *tensile strength* exert the strongest influence on the machinability of a film on a tubular-bag machine [65]. Bending stiffness plays the most decisive role of all.

Thin packaging materials with a *bending stiffness* up to 10 mN m^2 m^{-1} pose few problems in takeoff. Problems arise with materials of bending stiffness greater than 80 mN m^2 m^{-1}. Measures to reduce the takeoff forces include applying a powder to the packaging material or coating the machine components with Teflon. With machines that operate in cycles, webs of materials with large bending stiffness can easily break during processing, because the takeoff forces do not exist continuously but arise suddenly and generate high peak values of tensile stress. As a rule, the increased tensile strength associated with high bending stiffness cannot compensate for the greater peak loading to which the material is exposed during takeoff. To avoid any problems, the tensile strength of the packaging material should be approximately five times the expected takeoff forces.

The running properties of the packaging material, however, also depend on the adjustment and construction characteristics of the machine. The web tension generated is influenced by the line speed, the length of the bag, the geometry and material characteristics of the forming shoulder, and the design of the dancing roller system.

7.1.6. *Thermoforming of Polymers*

Thermoforming of packaging materials is used especially in the milk-processing industry. As shown in Figure 6, the packaging machine is fed with a roll of substrate that is drawn through a heating zone (contact or radiation heating) and passed to the forming station in which bowls or cups are molded via mechanical – pneumatic drawing. The material, which is firmly clamped in the forming station, is expanded and the wall thickness decreases in proportion to the relative increase in surface area. The characteristic dimension for the forming process is the so-called deep-draw ratio $H : D$, defined as the relationship between the height of the article H and the diameter D. The attainable deep-draw ratio is material dependent and also limited by the desired minimum strength of the package. Consistent wall thickness is difficult to obtain, which is of utmost importance because the thinnest area in the packaging has the greatest effect upon its gas barrier properties and mechanical loadability during stacking. Because the container must be removed from the form after thermoforming, the walls must be conical, with a taper between 1 and 2°. With typical packaging substrates, thermoforming temperatures lie between 110 and 170 °C. Immediately after thermoforming, the containers are filled and sealed by a film lid.

Figure 6. Principles of thermoforming

a) Film; b) Deep drawing die; c) Piston; d) Ejector; e) Cutting plunger; f) Cutting edge; g) Stretching plunger; h) Air channel; i) Plunger; j) Air vent

Comprehensive empirical investigations of thermoforming are discussed in [66]. Various quality criteria are important: these include expressions of the processing versatility, the deep-draw ratio relative to the drawing temperature and process, the attainable sharpness of the edges as representative of flow characteristics, and the wall thickness distribution. During thermoplastic deformation, an isotropic biaxial stretch is a prerequisite if the container is to demonstrate the necessary impact strength. The relationship between deep-draw ratio and draw temperature is characteristic for each type of polymer; it also depends upon the film thickness and the drawing process. The optimum drawing temperature for PVC is 110 °C and for PS, 140 °C. Deep-drawing properties of films, determined under laboratory conditions, should always be confirmed by machine trial carried out under production conditions; as a rule, larger temperature deviations can be expected because of the increased film widths and multicavity forms involved in scale up.

Deep Drawing of Aluminum Laminates. Film laminates that include aluminum foil are frequently employed in food packaging because the aluminum layer imparts a barrier to gases, flavors, and light (see Section Aluminum-Polymer Laminates). On thermoforming such laminates however, problems arise due to the extremely low extension at break of the aluminum, which can thus be torn easily. Although an aluminum rod can have an extension at break of ca. 30 %, this is reduced to ca. 3 % for a 12-µm foil because of the grain structure of the aluminum. The strain properties of an aluminum – polymer laminate are governed by the thickness of the aluminum, the quality of lamination, and the extension at break of the polymer substrate. The lower the extension at break of the polymer, the higher is the potential elongation of the aluminum foil within the laminate. Depending upon the film substrate, strains between 5 and 25 % can be achieved with laminates to a 15-µm aluminum foil, without the formation of visually detectable pinholes [67]. Clearly, however, in comparison to polymeric films, only low deep-draw ratios are possible with aluminum laminates. For this reason, such packaging materials are used preferably to manufacture shallow dishes and bowl-shaped containers. The greatest drawing depth is obtained by using a rounded form, although rectangular containers are more economical because of the lower amounts of scrap generated during stamping. Depending on the construction of the laminate, the packaging container may be filled with hot material or, after filling, may be sterilized in an autoclave.

7.1.7. *Processing Folded Boxes*

During the processing of cardboard panels or collapsed folded boxes on binding machines, the erectile behavior of the cardboard is the decisive characteristic for determining machinability. The quality of the creases is primarily responsible for this behavior. During creasing, the areas corresponding to the edges of the finished box are exposed to shear forces that weaken the bonds between individual layers of fibers and cause ply separation on bending. Hence, when the box is being set up, a hinge effect is generated along the crease. Tests designed to judge the quality of creases have shown that the bending-moment ratio (i.e., the relationship between the bending moments of a creased and a noncreased cardboard sample) is a reliable estimate of machinability [68], [69].

7.1.8. *Closing and Sealing Boxes*

Boxes made of corrugated cardboard are often sealed automatically with gummed or adhesive tape. Gummed tapes are tapes made of kraft paper with a coating of water-activated gum. Today, the adhesive normally contains chemically modified vegetable glues. Adhesive tapes based on polymer films coated with an autoadhesive, generally a synthetic material, can also be used. The strength of the adhesive tape, regardless of type, is decisive in determining the mechanical load that a carton can withstand. The strength of a sealed box is determined by means of falling and stacking tests [70].

7.2. Product Dosage in Packaging Machines

The centerpieces of all filling plants are the dosage units or filling machines. According to DIN 8740, Part 2, filling machines are packaging machines that introduce the product—in precisely determined amounts—into the packages [71]. Solid and liquid products can be metered quantitatively according to weight or volume. An exception with solid materials is the dosage based on number of items. Accordingly, filling machines are divided into gravimetric filling machines, volumetric filling machines, and counting filling machines.

7.2.1. *Gravimetric Dosage*

Gravimetric filling machines are subdivided into *net weight filling machines*, which weigh out a predetermined amount before introducing the contents into the packaging substrate, and *gross weight filling machines*, which weigh out a predetermined amount together with the packing substrate during filling – with or without tare adjustment. Figure 7 shows a gravimetric filling machine. According to the type of monitoring characteristics gravimetric filling machines may be mechanical or electrical. In most cases, the products is fed to the weighing mechanism via a two-stream principle. Most of the contents come from a coarse stream, and the target weight is made up subsequently from a fine stream (see Fig. 7). The dosage precision increases with decreasing mass flow of the fine stream.

Figure 7. Gravimetric filling machine

a) Feed funnel; b) Coarse filling; c) Fine filling; d) Electronic dosage; e) Weighing tank; f) Controller; g) Discharge pipe

With discontinuous dosage, inaccuracies in the amount of material fed can occur due to inconsistencies in the transport mechanism in the weighing chamber [72]. Apart from this, dosage errors caused by the product sticking to the weighing cells are also possible.

7.2.2. *Volumetric Dosage*

Filling machines that operate on volumetric principles are divided into *dosage filling machines* and *level filling machines.* Dosage filling machines include measuring cup, displacement, piston, and rotary filling machines. Level filling machines, in which a certain dosage is determined by the packaging substrate, include vacuum, gravitational, and pressure filling machines.

The dosage capacity of a packaging machine is described primarily by the dosage rate and precision. Investigations of the bulk material behavior associated with measuring cup dosage incorporated into vertical tubular-bag machines are described in [73]. Filling time calibration curves, which illustrate the relationship between dosage size and required filling time, are helpful in determining product-specific properties when attempting to optimize the line speed of a packaging machine.

Auger filling is another means of volumetric filling. Here, the desired dosage is determined by the number of revolutions of a horizontally or vertically positioned metering screw. Auger filling is employed preferentially with materials that lead to high levels of dust formation but, at the same time, are not easily broken. Dosage inaccuracies can be caused by uncontrolled metering of the product by the screw or by the product sticking to the screw. In comprehensive studies of the technology and accuracy of auger dosage aggregates, both short-term precision and long-term errors were considered in judging various systems [74].

7.3. Robots in Packaging

According to VDI guideline 2860, industrial robots are described as universally applicable pieces of apparatus capable of movement in many axes, where the movement as defined by the order of movements or the distance and angle of movement is freely programmable (i.e., can be altered without mechanical modifications), and which in certain circumstances are controlled by sensors [75]. Robots can be equipped with grips, tools, or other equipment necessary for manufacturing purposes and can carry out handling or manufacturing routines. In the packaging sector, robots can be employed to fill packaging substrates with solid articles, to stack packed items, and to commission transport units. Product handling is carried out either mechanically with the aid of grip mechanisms or pneumatically with suction caps. Working cycles can be classified into those that are controlled by programming and those in which optical or acoustic sensors are involved. In the food-packaging sector, robots equipped with optical detector systems are used which can recognize chocolates being transported on a conveyor belt and individually place them in a tray. Packaging robots are particularly common where individual packages (e.g., plastic bottles) must be placed in boxes for transporting. In general, however, robot technology is rarely

employed in the packaging industry. The reason for this lies in the relatively low working speeds compared to conventional packaging aggregates, coupled with the high investment costs for machines and programs.

7.4. Aseptic Packaging

The principal aim in food packaging is to maintain product quality. To avoid thermal damage to foods during sterilization of the package, techniques have been developed over the past three decades which enable packages (originally of liquids) to be filled under aseptic conditions. This has been extended more recently to include partially solid foodstuffs. During aseptic packaging, the contents and package are sterilized in separate operations. Subsequent dosage and sealing processes are then carried out under aseptic conditions. The aseptic packaging of foods is currently one of the fast-developing areas of packaging technology [76]. Sterilization of the packaging material is a central step in aseptic packaging. It is normally carried out in hydrogen peroxide solution at increased temperature. Sterilizing processes involving ozone, sulfur dioxide, peracetic acid, heated air, and steam are also available which can be used for certain products as well as packaging substrates. The sterilizing effect of concentrated hydrogen peroxide solution was investigated as a function of concentration and temperature by using *Bacillus subtilis* spores [77]. Optimal sterilization was observed at hydrogen peroxide concentrations between 45 and 50 %.

Because in aseptic plants that function on a continuous basis, sterilization must be ensured within several seconds, the hydrogen peroxide solution has to be heated to 80 – 90 °C. An employer utilizing such aseptic packaging equipment is required to take the necessary measures to guarantee the health and safety of his employees. This involves determining the hydrogen peroxide emission from the system [78].

[Top of Page]

8. Interaction between Packaging and Food

Albert L. Baner, Rainer Brandsch, Otto Piringer

Today, food and packaging constitute an indivisible unit. Proper food packaging requires that the properties of the components — the food and the packaging — are combined in an optimal way. The interaction between packaging and food consists of the transfer of substances from the environment through the packaging and from the packaging into the food and vice versa (see Fig. 8). Chemical reactions inside the packaging or food are also possible. Not only can the quality of the packed food change as a result of such interactions, but the properties of the packaging may change as well, and this can lead to further loss of its protective function. Hence, the main criterion for an optimal packaging system is, in most cases, minimal interaction. General references are given in: [123-131].

Figure 8. Mass transfer in packaged food

m_E= mass transfer from the environment (E); m_P= mass transfer from the packaging (P); m_F= mass transfer from the food (F)

8.1. Physical Interactions

Kinetic (diffusion) and thermodynamic (partitioning) processes are the most important physical interactions. In a diffusion process, the mass transport occurs in the direction of a concentration gradient as a result of random molecular motion. One can write the general equation for the mass transport by diffusion in the direction of the *x*-axis, according to Fick's 2nd law [132]:

$$\frac{\delta c}{\delta t} = D\frac{\delta^2 c}{\delta x^2} \quad (1)$$

where *c* is concentration, *t* time, *x* distance, and *D* the diffusion coefficient (constant).

Solving the diffusion equation gives the concentration contribution at each point in time and at each location on the *x*-axis. Simplifying approximations make analytical solutions possible.

8.1.1. *Permeation*

Under steady state conditions, $\delta c/\delta t = 0$ and, as in the case of permeation, the equation of diffusion reduces to Fick's 1st law [132], which expresses the flux *J* as the amount of matter passing through a unit area of a film in unit time:

$$J = -D \cdot \frac{dc}{dx} \quad (2)$$

A typical example for a packaged food is the permeation of gases into or out of the package. From Fick's 1st law one can obtain:

$$J = P \cdot \frac{\Delta p}{d} \quad (3)$$

where Δp is the partial pressure difference of the permeating gas between the exterior and interior of the packaging, *d* is the thickness of the packaging, and *P* is the permeability coefficient. If the solubility coefficient *S* in the packaging is defined as $S = c/p$ (the ratio of the concentration *c* of the gas in the packaging to the partial pressure *p* of the gas in equilibrium with the packaging), then $P = D \cdot S$, where *D* is the diffusion coefficient.

Many different units can be used to express *P*. Values can vary over several orders of magnitude, depending on the properties of the material. The values are tabulated in polymer handbooks and manufacturers literature [133]. For a given shelf life of a particular foodstuff, Eq. (3) can be used to calculate the thickness of packaging material and the barrier properties required for an allowable flux of gas into or out of the package (see Section Barrier Polymers). A frequently used example is calculation of the maximum water-vapor flux for a packaging containing a water-sensitive product.

8.1.2. *Migration*

Migration from Packaging into Food. Most interactions involving mass transfer between the packaging and food take place under non-steady-state conditions and are referred to as migration. Migration from the packaging (e.g., polymer film) into the food (e.g., a liquid) can be described by using Fick's 2nd law. As mentioned above, analytical solutions for the diffusion equation can be obtained under simplifying assumptions. In the simplest case it is assumed that the thickness of the packaging is infinite, and the solubility of the migrant in the well-mixed liquid is high. Assuming that the migration process is far away from equilibrium, one can obtain the simple expression:

$$\frac{m_{\mathrm{F,t}}}{A} = \frac{2}{\sqrt{\pi}} c_{\mathrm{P},0} \rho_{\mathrm{P}} \sqrt{D_{\mathrm{P}} t} \tag{4}$$

where $m_{F,t}$ is the amount of the migrated compound, *A* the contact area, $c_{P,0}$ the initial concentration of the migrant in the polymer, ρ_P the density of the polymer, D_P the diffusion coefficient of the migrant in the polymer, and *t* the contact time.

Equation (4) shows that the material transport from the packaging material into a well-mixed liquid is proportional to the initial concentration of the migrant in the polymer, the square root of time, and the square root of the diffusion coefficient. Most stringent is the timeframe (small *t* values) or, in other words, the limit of applicability beyond a mass transfer of more than ca. 60 %. If this conversion is exceeded, which often happens, and the system runs close to the equilibrium state, high overestimations or even aberrations of the calculated mass transfer into the liquid can occur.

To overcome this limitations one must use the more general solution of the diffusion equation [134]. It is assumed that at the beginning of mass transfer the migrant is homogeneously distributed in the polymer, there is no boundary resistance for transfer between polymer P and liquid food F, and the total amount of the migrant in P and F remains constant during the migration process. The diffusion of the migrant in the polymer is assumed to be several orders of magnitude slower than diffusion in the liquid phase (e.g., mixed during transport), and the diffusion coefficient of the migrant in the polymer is constant.

$$\frac{m_{\mathrm{F,t}}}{A} = c_{\mathrm{P},0}\, \rho_{\mathrm{P}} d_{\mathrm{P}} \left(\frac{\alpha}{1+\alpha}\right) \left[1 - \sum_{n=1}^{\infty} \frac{2\alpha(1+\alpha)}{1+\alpha+\alpha^2 q_n^2} \exp\left(-D t \frac{q_n^2}{d_{\mathrm{P}}^2}\right)\right] \tag{5}$$

$$\alpha = \frac{V_{\mathrm{F}} / V_{\mathrm{P}}}{K_{\mathrm{P,F}}}$$

where $m_{F,t}$ is the amount of migrated compound, *t* the contact time, *A* the contact area, $c_{P,0}$ the initial concentration of the migrant in the polymer, ρ_P, ρ_F the density of the polymer and the liquid food, d_P the thickness of the polymer, D_P the diffusion coefficient of the migrant in the polymer, V_P and V_F the volumes of the polymer and the liquid food, $K_{P,F} = c_{P,\infty}\rho_P/c_{F,\infty}\rho_F$ the partition coefficient [the ratio of the migrant concentration (w/v) in the polymer and the liquid food at equilibrium], and $\tan q_n = -\alpha q_n$ (q_n are the positive roots of the trigonometric identity).

Due to good mixing in the initial stage of migration, the total amount of the material is transported away from the contact layer into the volume of the liquid, and the concentration in the contact layer drops to zero. The rate of diffusion of the migrant out of the package is the rate-determining step. With longer migration times, the partition coefficient begins to play a deciding role through the α value. Especially for $\alpha \ll 1$ ($K_{P,F} \gg 1$), only a very small fraction of $c_{P,0}$ migrates into the liquid.

As an example, estimations were made for a conventional EC packaging (cube of 1 kg with a surface area of 6 dm^2), made from a high-density polyethylene (HDPE) film 50 µm thick containing 1000 ppm of the antioxidant Irganox 1076 (M_r = 531 dalton). The assumed test conditions are 10 d at 40 °C and the diffusion coefficient of the antioxidant in the HDPE matrix is $D_P = 2.9 \times 10^{-10}$ cm^2/s. The resulting migrant concentration in the foodstuff as a function of time is shown in Figure 9. It is evident that the estimation made with Equation (4) gives fair values for conversions below 60% of the maximum amount of 3 mg/kg. As the system approaches the equilibrium state an increasing overestimation is made. The estimation made with the more general Equation (5) gives precise results under the assumption that $K_{P,F} = 1$. The main reason for this discrepancy is the assumption of an infinite polymer volume made for Equation (4). Only by taking into account the finite volume of the polymer, as in Equation (5), can the correct migrant concentration in the foodstuff in the vicinity of the equilibrium state can be estimated.

Figure 9. Migration estimation for the antioxidant Irganox 1076 (1000 ppm) into foodstuff from a conventional EEC packaging made from HDPE (50 µm). Dashed line: estimation made with Equation (4); solid line: estimation made with Equation (5).

For viscous or solid food the simplifying assumption of a well-mixed liquid must be abandoned, and the system, as well as

the possibility of finding an analytical solution for it, becomes more complicated. One must take into account the diffusion coefficient of the migrant in the solid foodstuff, which is often in the same range as in the packaging material. This has been done in a simplified way in the following expression derived from Equation (4):

$$\frac{m_{F,t}}{A} = \frac{2}{\sqrt{\pi}} c_{P,0} \rho_P \frac{\beta}{1+\beta} \sqrt{D_P t} \tag{6}$$

$$\beta = \frac{1}{K_{P,F}} \sqrt{\frac{D_F}{D_P}}$$

where D_F is the diffusion coefficient of the migrant in the food.

For $D_F \gg D_P$ and $K_{P,F} \leq 1$ we obtain Equation (4). If the diffusion coefficients in the packaging and in the food are approximately equal, the partition coefficient, $K_{P,F}$ determines the transport through the system. The packaging determines the rate of the whole process if the migrant dissolves much better in the food than in the packaging ($K_{P,F} \leq 1$) and the food determines the rate of the whole process, if the migrant dissolves much better in the packaging than in the food ($K_{P,F} \gg 1$). If $D_F < D_P$ the mass transport is determined by the diffusion coefficient in the food D_F and the partition coefficient $K_{P,F}$. This leads to the buildup of a concentration profile in the foodstuff.

An exact analytical solution of the differential equation that takes into consideration the diffusion in food and finite values for V_P and V_F is not available, and as a consequence the application of numerical methods is necessary.

Migration from Food into Packaging. In principle there is no difference in the mathematical treatment of the mass transfer from food into packaging compared to the reverse phenomenon described above. While in the initial phase the mass transfer of the migrant from the package into the liquid is independent of the partition coefficient, the migration from the liquid into the package is proportional to K. The partition coefficient plays a decisive role in the dissolution (sorption) of a migrant in the packaging layer in contact with the liquid. For high K values the total amount of sorbed material is concentrated in a thin layer of packaging material in contact with the liquid, and the transport process in the initial stage is independent of the material thickness.

Food packaging interactions include the uptake of major food components, such as fats and oils or water, by the packaging material. If high enough, such absorption can cause swelling and changes in the properties of the polymer. This swelling can lead to increased migration of additives from the polymer because their diffusion coefficient increases by several orders of magnitude [135]. Other consequences of swelling are structural changes that occur in the polymer, which may lower the mechanical properties of the packaging. The possibility of swelling is an important consideration in food packaging compatibility.

8.1.3. *Prediction of Diffusion Coefficients*

To use Equation (5) in practical cases data for two fundamental constants are needed: (1) the partition coefficient $K_{P,F}$ of the migrating compound between the polymer P and the foodstuff or simulating liquid F and (2) the diffusion coefficient D_P of the migrant in P. So far upper limits for migration amounts are needed from the regulatory standpoint; predictions of “worst-case” scenarios can start with the assumption of good solubility of the migrant in F, and consequently $K_{P,F} = 1$ can be used. Much more complicated is the prediction of an adequate value for D_P.

Much work has been done in correlating polymer structure with migrant structure to predict migrant diffusion in the polymer [136]. From a practical viewpoint, most of this work has limited value in predicting the diffusion behavior of substances in food packaging systems because of their complex nature.

In the food packaging sector polyolefins, especially polyethylene (PE) and polypropylene (PP), are the most widely used plastic materials. Because PE and PP have a rather low glass transition temperature T_g, it is legitimate to assume that under normal conditions of use the migration of substances in and from packaging made from these materials obeys the laws of diffusion. It has been shown that the migration in some non-polyolefin polymers such as polystyrene (PS), poly(ethylene terephtalate) (PET) and polyamide (PA) also follows the laws of diffusion.

To estimate upper limits of migration values from Equation (5), a simple semi-empirical formula for the estimation of D_P was developed recently [129], [137], [138]:

$$D_P = D_0 \exp\left(A_P - 0.1351\, M_r^{2/3} + 0.003\, M_r - \frac{10454}{T}\right) \tag{7}$$

where $D_0 = 1\ m^2/s = 10^4\ cm^2/s$, M_r is the relative molecular mass of the migrant, and T the temperature in kelvin.

The parameter A_P has the role of a “conductance” of the polymer matrix towards the diffusion of the migrant. Higher values of A_P in such polymers as PE lead to increased D_P values, while in stiff-chain polymers, such as polyesters and polystyrene, lower A_P values take into account the smaller diffusion coefficients for the same migrant. The equation can be used for $M_r \leq 4000$ dalton.

To calculate migration rates with a sufficient safety margin from the regulation standpoint (see Section Legal Aspects) it is

possible to match the parameter A_P in Equation (7) to yield a "worst-case" value A_P^*, which leads to a corresponding D_P^* instead of the real D_P. Due to the scatter of experimental values, the use of $D_P^* \geq D_P$ can avoid underestimations with a certain statistical degree of assurance (e.g., 95 %). The greater the scatter, the higher the upper limit for D_P^* must be set. This statistical assurance is a matter of convention and can be established from a regulatory point of view.

A consequence of the above consideration is a periodical change in A_P^* values depending on available data collections. A_P^* is a function of temperature: $A_P^* = A_P' - \tau / T$, where the parameter τ, with the dimension K, accounts for a specific contribution of the polymer matrix to the diffusion activation energy. Table 2 lists values of A_P' and τ for different polymers.

Table 2. Values of A_P' and τ different polymers

Polymer*	A_P'	τ
LDPE	11.5	0
HDPE	14.5	1577
PP	13.1	1577
PS	0.0	0
HIPS	1.0	0
PET	6.0	1577
PA	2.0	0

* LDPE = low-density polyethylene, HDPE = high-density polyethylene, PP = polypropylene, PS = polystyrene, HIPS = high-impact polystyrene, PET = poly(ethylene terephthalate), PA = polyamide.

For the polyolefins another semi-empirical diffusion model has been developed [139], from which it is it is possible to arrive at the following relationship:

$$D_P = a \cdot \exp\left(bM^{1/2} - k \cdot \frac{M^{1/3}}{T}\right) \; [\mathrm{cm^2/s}] \tag{8}$$

where *a*, *b*, and *k* are empirical constants determined from experimental diffusion data. The values for polyolefins are given in Table 3.

Table 3. Values for *a*, *b*, and *k* for Equation (8)

Polymer*	ln *a*	*b*	*k*
LDPE	– 4.16	0.555	1140.5
HDPE	0.90	0.819	1760.7
PP	– 2.10	0.597	1335.7

* For explanation of abbreviations, see Table 2.

The main limitation in estimating migrations for legislative purpose with the diffusion model of **Limm** and **Hollifield** is underestimation in some cases. Various programs are available for estimating the specific migration of packaging compounds [140-142].

8.1.4. *Multilayer Structures*

In Section Prediction of Diffusion Coefficients a practical situation is reduced to an idealized system in which the plastic material is a single-layer structure with a finite thickness and a homogeneously distributed migrant. Hence, the initial and boundary conditions for the analytical solution of the diffusion equation (5) are fulfilled. In the general case of structures with more than one layer or variable diffusion coefficients, only numerical mathematics lead to the desired result. Basically, this means restricting the solution of the diffusion problem to a set of grid points, conveniently distributed within the integration domain, and approximating the involved derivatives by discrete schemes [12].

The diffusion problem in a multilayer polymer system can be solved numerically, each layer $k = 1, 2, \ldots n$ having diffusion coefficient D_k, density ρ_k, thickness d_k, the laminate being in contact with a foodstuff medium of mass m_F and density ρ_F. The migration of a compound is governed by partial differential equations of diffusion for each layer *k*.

Under steady-state conditions the permeation through the multilayer structure is dominated by the laminate layer with the lowest permeability:

$$\frac{d}{P} = \frac{d_1}{P_1} + \frac{d_2}{P_2} + \cdots + \frac{d_n}{P_n} \tag{9}$$

where d_k is the thickness of layer *k* and P_k the permeability of layer *k*.

Therefore, the presence of a thin barrier layer with low *P* can determine the permeation characteristics of a multilayer structure. Figure 10, shows schematically the development of the migrant concentration with time in the foodstuff. Due to the barrier layer, the system needs a period of time, the time lag θ, until the steady state regime is reached and a linear dependence of the concentration with time is observed. The slope of the linear part of the graph is an indication for the efficiency of the barrier layer.

Figure 10. Schematic representation of the permeation through an multilayer structure with a barrier layer (θ = time lag)

8.1.5. *Non-Fickian Processes*

The preceding discussion holds true only if the diffusion and partition coefficients are constants. However, in some cases D_P and *K* can be functions of a concentration gradient in the polymer and can vary with time. If the migrant causes extensive swelling, diffusion can no longer be described by the concentration dependence of Fick's 2nd law [134], [135].

At very low migrant concentrations in the polymer, the migration rate may no longer be proportional to its concentration in the polymer. For example, active sites within the polymer matrix may tend to bind a migrant and thus decrease the possibility of its transfer from the polymer to the food-contacting phase.

In many cases, the observed transfer of additives is due not to migration but to removal of material from the polymer surface in contact with the food. During manufacturing of the packaging material, some of the additives are forced to the surface of the polymer. Subsequent contact with food, often in the initial period of contact (e.g., pasteurization), removes this surface layer of additives. After removal of this layer, a much slower diffusion-controlled migration occurs.

In the case of paper and board, physical interactions and the transfer of migrants to foods are controlled by sorption processes. Migration is governed by sorption isotherms, and the prediction of migration from paper materials is difficult because of their very different structures, compositions, and manufacturing processes.

8.2. Chemical Interactions

Much is known about reactions involving gases and water vapor with food (⟶ Foods, 2. Food Technology) [143]. From the packaging point of view, only the maximum allowable transmission of gases during the shelf life needs to be known to specify the package. With this knowledge, the maximum allowable package permeation rate (see Section Permeation) can be estimated.

8.2.1. *Production of Off-Odors*

Because of the complex structure and chemical composition of package systems, a variety of chemical reactions can occur during package manufacture and use. These reactions occur between some packaging components, whereby other components act as catalysts, to produce substances with low odor thresholds. In the manufacture of packaging materials, various processes can produce off-odors, for example, the surface treatment of polyolefins by corona discharge. These substances then migrate through the material during storage and lower the quality of the packed product. Such odor-producing substances need not to be formed during manufacture but may develop over the shelf life of the product (e.g., a continuous reaction taking place in the presence of a metal). These substances diffuse slowly into the product and their presence is not detected initially. However, defects and possible complaints arise after the product is on the market. Identification and analysis of these products is very difficult; many isolation and concentration steps are required because the odor thresholds are too low to be analytically detectable. Furthermore, a combination of instruments (e.g., GC-MS) coupled with sensory evaluation is necessary to identify and quantify these substances [129].

Unsaturated carbonyl compounds, particularly $C_6 – C_{10}$, are an important class of odor-producing substances because they occur in nature, have low thresholds, and are relatively stable due to their conjugated double bonds. Other oxygen- and sulfur-containing compounds and some hydrocarbons are important off-odor compounds.

8.2.2. *Other Reactions*

A list of important classes of reactions that can occur between food and packaging materials follows. This field of research is relatively new, and for this reason, in combination with the complexity of analysis and detection, very little information and few data are available on actual reaction products.

1. Hydrolysis or decomposition of additives migrating into food can occur. Little is known about these reactions because they are very complex and occur only at trace levels [144].
2. Reactions occurring at high temperature are becoming more important as packages are used in high-temperature applications in microwave and conventional ovens.
3. Chemical sterilization and irradiation of package materials can generate decomposition products [145].
4. Corrosion of metals and their reaction products are important factors in metal containers [146].

Despite the many possibilities for food packaging interactions mentioned above, in practice complaints and problems arising from these interactions occur relatively seldom.

8.3. Measurement Methods and Migration Limits

8.3.1. *Measurement Methods*

The purpose of migration testing is to ensure food safety and protect the consumer by controlling the extent of mass transfer of undesirable constituents from the packaging to the foodstuff. A distinction is made between migration testing, in which mass transfer is subject to the laws of diffusion and partitioning, realized under conditions in which the packaging material withstands food contact without altering its mechanical and diffusion properties, and extraction, in which the solvent penetrates the packaging material and changes its diffusive and mechanical properties.

The control of material transfer from plastic packaging materials into food is manly based on the measurement of substances in the food or a food simulant after certain specified and in most cases standardized contact conditions. Adequate migration cells made of glass or stainless steel are used. The packaging material is completely immersed in the liquid or contacts the simulant from one side. Conventional migration measurements keep a sample in contact with the food or simulant in a manner that represents the actual conditions of use. In alternative migration tests, the sample is kept in contact with an appropriate simulant in such a manner that a strong interaction between packaging and simulant occurs. By using shorter contact times and/or higher temperatures (more severe test conditions) at least equal or even exaggerated extents of migration are obtained.

Beside the geometric dimensions of a given food packaging system which influence migration, mass transfer from a plastic into food and vice versa is governed by kinetics (diffusion in the polymer and foodstuff) and thermodynamics (equilibrium partitioning between packaging and food; see Section Physical Interactions). It is common practice in migration evaluations to start as a worst-case assumption with a total mass transfer scenario in which the initial concentration of a migrant in the packaging is known. However, if this relatively simple calculation provides a scenario which exceeds a migration limit, then it is advisable and necessary to achieve further refinements to the total mass-transfer approach.

When selecting a method of analysis, some pre-considerations are obligatory. The volatility of the analyte must be taken into account, as well as the nature of the matrix to be analyzed and, in particular, the expected concentration range of the substance being measured. Generally, these methods should allow one to quantify the monomer or plastic additive at the required restriction limit in all relevant food simulants and/or in the polymer. It is generally recognized and accepted that analytical methods must be suitable for the intended use. The analytical procedures for compliance testing with food laws are to be carried out on the basis of validated methods as specified in ISO 5725 based on round-robin tests, with well-defined repeatability *r* and reproducibility *R*.

Validation and standardization of analytical methods is a recognized basic task of CEN. The Technical Sub-Committee CEN TC194/SC1 “General Chemical Methods of Testing for Materials Intended to Come into Contact with Food” is active in developing standardized analytical methods and specific migration test methods. There have been many efforts to standardize migration measurements as laid down in the EN/ENV Standards. The EN/ENV 1186 series is concerned with the testing required by the European Commission Directive relating to plastic materials and articles intended to come into contact with food (90/128/EEC), and is intended to give advice on the selection of the most appropriate test conditions and test methods for a given application of a plastics article [147]. Fully validated methods have been developed for 15 plastics monomers and published as European pre-norms in the ENV 13130 series [148].

The sample for testing should be taken from the final article in its ready-for-use state. Different cell types for one-side testing are described in Part 1 of EN/ENV 1186. The most commonly used test conditions are 10 d at 40 °C, which simulates conditions of actual use in which the contact time is longer then 24 h at 5 – 40 °C. More detailed conditions for overall and specific migration tests, are given in Parts 2 – 15 of EN/ENV 1186 and the EEC directive 82/711/EEC and its amendments (see Section Legal Aspects).

For specific migration testing there is a clear need for pragmatic and cost-effective solutions. To reduce the amount of analytical work without compromising the requirements of consumer protection the concept of functional validation and precision is introduced. This means that the number of validation steps to be applied and the amount of precise data needed is a function of the analytical demands and the relevance of the migrant concerned.

State of the art analytical methods for qualitative and quantitative determination of migrants use gas chromatography (GC), high-performance liquid chromatography (HPLC), mass spectrometry (MS), and combinations thereof.

8.3.2. *Migration Limits*

Any migration control procedure must be linked either directly or indirectly to the measurement or evaluation of the concentration of all undesired substances. This concentration represents the toxicologically relevant target parameter for any migration-control methodology. The toxicologically relevant molecular mass range for migrants is considered to end at a molecular mass of 1000 g/mol. Larger molecules are considered from a biophysical point-of-view not to be physiologically absorbable in the gastrointestinal tract. The toxicologically relevant target parameter can be measured, controlled, or assessed in different ways and must then be compared to relevant migration limits set by regulations such as the European Commission Directive 90/128/EEC and its amendments, the United States Code of Federal Regulations (CFR), title 21, parts 170 – 199, the Food Sanitation Law in Japan, or by nonmandatory but practically binding recommendations (see Section Interaction between Packaging and Food).

In the EC migration limits are set in terms of “global migration limits” (GML = 60 mg/kg food) and “specific migration limits” (SML, in µg/kg or mg/kg food) from a package into a foodstuff or food simulant under given contact conditions. SMLs are directly calculated from the toxicological characteristics of the specific substances, expressed as acceptable daily intake (ADI) or tolerable daily intake (TDI) in µg/kg body weight, by multiplying them by the factor 60 (the average weight of a European is assumed to be 60 kg). Because it is further assumed that one person consumes 1 kg of foodstuff per day, the SML value can be compared directly with the migration data if expressed in milligrams or micrograms per kilogram of food simulant or real foodstuff. The correlation between area- and mass-related migration data can be made by the accepted assumption that 1 kg food is contacted with 6 dm^2 of packaging material (conventional EC packaging). If the SML is set as “not detectable” in the foodstuff, the SML corresponds to the “limit of detection” (LOD) of the method indicated for the determination of the migrant, which is usually in the range of 10 µg/kg food simulant or foodstuff. (For further details see

Section European Community).

On the other hand, food packaging legislation or regulation has also set up restrictions on the packaging material side. Such compositional limits in plastics are given as “maximum quantity limits” (QML).

In the United States a somewhat different approach is used. Instead of calculating from the SMLs toxicological data and comparing them with migration data, the FDA uses migration data to calculate the “estimated daily intake” (EDI), which is then compared directly with the corresponding ADI or TDI values. The EDI is calculated by multiplying the concentration in the daily diet, based on “consumption factors” (CF) and “food type distribution factors” (f_T), by a factor of three (it is assumed that one individual consumes 3 kg liquid and solid food per day). Finally the FDA established a concentration in the daily diet of 0.5 μg/kg (ppb) as the threshold of regulation for substances used in food contact articles. (For more details see Section United States).

Migration of packaging components must be also controlled for sensory reasons. Residual solvents and other components from printing, laminating, and lacquering operations are examples of nontoxic but sensorially active substances. These substances can produce off-odors, and their limits must be established in accordance with their odor thresholds. Migration of these nontoxic substances is acceptable as long as their level remains under the sensory threshold. No official limits exist because they are too difficult to establish owing to the wide range of thresholds, which also depend on the type of food product. For unsaturated carbonyl compounds the odor threshold is 10^{-4} mg/m^3 and even lower for other substances [149]. Many factors influence the odor threshold in packaged foods, such as the partition coefficient, the ratio of the package area to the food mass, the temperature, and the composition and intensity of the aroma, to name a few [129]. In some countries, standards for testing the odor intensities of packaging materials have been developed [150].

8.4. Legal Aspects

8.4.1. *General Requirements*

The role of packaging in food legislation has been realized since the early 1900s. However, the importance of mass transfer of substances from the packaging to the food has been considered only since the 1950s, when the variety and complex chemical composition of packaging materials were recognized.

Realistic evaluation of the health risk associated with packaging is necessary. With the present state of the art, the amounts of substances transferred from the packaging to the food are so low that health hazards can be considered under the aspect of the chronic toxicity of the migrants. The risk-to-benefit ratio for pre-packed food is negligible compared to that for unpacked food. Even though this is unarguable, care must be taken to ensure consumer safety. Thus every regulation should consider the following points: 1) the transfer of substances from packaging into food is, in principle, undesirable and 2) unavoidable mass transfer in state-of-the-art packaging should not be prohibited if the substances do not constitute a health hazard and are technically unavoidable in an optimized package system. The principal optimization criteria for packaging are the protection of foods, consumer safety, environmental compatibility, and low cost. Meeting the above two points benefits the consumer and encourages technological progress.

To minimize mass transfer from packaging to food, the mass transfer must be quantified. Great uncertainty exists about setting limits on the allowable quantity of migration into foods, and the following points must be considered. Besides the acute toxicological properties of substance in packaged food, the chronic mutagenic and carcinogenic activity of transferred substances is most important. The application to humans of the results of no toxic effect level (NTEL) experiments on animals and the validity of subsequently derived ADI values are very uncertain. EDI levels have additional uncertainties arising from regional and temporal considerations. The kinds and amounts of food consumed vary with season, geography, and socioeconomic or ethnic background.

The amount of substances transferred from the packaging to the foodstuff can vary over a large range. The theory of diffusion can be used to estimate mathematically the quantity of material transferred (see Section Migration). However, many other complex factors affecting migration cannot be anticipated (see Section Non-Fickian Processes).

The permissible level of components from packaging in food are a function of the above considerations. As a consequence of these uncertainties, all substances can be divided into categories according to their health risk, which than can be used as a basis for regulation [128]. One end of the spectrum consists of substances that poses no risk (substances which are inert or naturally occurring and are toxicologically inactive), and at the other end are substances that must be excluded from packaging because they are recognized as toxicologically dangerous. Between this two extremes are the remaining substances, which require more or less detailed toxicological or migration studies from which useful limits can be derived. When the need to limit the use of a substance has been recognized, statistically reliable analytical methods are required which can be used by industry and control laboratories around the world. Once the limit for a substance is set, the means for maintaining this limit in practice must be determined.

8.4.2. *European Community*

The European Commission initially drew up a first framework directive 76/893/EEC, which was amended by a new framework directive 89/109/EEC and establishes two general principles:

1. The principle of the “inertness” of the material and the “purity” of the foodstuffs, whereby the materials and articles must not transfer any of their constituents to foodstuffs in quantities which could “endanger human health and bring about an unacceptable change of the composition of the foodstuff or deterioration in the organoleptic characteristics thereof”.
2. The principle of “positive labeling”, whereby materials and articles intended to come into contact with foodstuff must be accompanied by the words “for food” (or an appropriate symbol 80/590/EEC) [151].

The new framework directive laid down, in confirmation of the above-mentioned principles, the sectors in which the

Commission is asked to establish Community rules and the criteria and procedures to be followed in the drafting in specific directives. The Commission must, as far as possible, satisfy rigorous health criteria and thus consult the Scientific Committee for Food (SCF, set up in 1974 by a Commission Decision, is a independent advisory body consisting of leading figures from the fields of toxicology, nutrition, medicine, etc.). Specific directives and amendments to existing directives will be adopted by the Regulatory Committee procedure, in this instance the Standing Committee on Foodstuffs (CPDA, Council Decision 69/414/EEC).

First Framework Directive	76/893/EEC
New Framework Directive	89/109/EEC
Symbol Directive	80/590/EEC
Plastics: Directive on Vinyl Chloride Monomer (VCM)	78/142/EEC
Plastics: Directive on the Methods for Determining VCM in PVC	80/766/EEC
Plastics: Directive on the Methods for Determining VCM in Food	82/432/EEC
Plastics: Directive on the Basic Rules for Migration Testing	82/711/EEC
1st Amendment	93/8/EEC
2nd Amendment	97/48/EEC
Plastics: Directive on the List of Simulants	85/572/EEC
Plastics: Base Directive: Monomers	90/128/EEC
1st Amendment	92/39/EEC
2nd Amendment	93/9/EEC
3rd Amendment	95/3/EEC
4th Amendment	96/11/EEC
5th Amendment	99/91/EC
6th Amendment	2001/62/EC
Regenerated Cellulose	83/229/EEC
1st Amendment	86/388/EEC
2nd Amendment	92/15/EEC
Regenerated Cellulose Codification	93/10/EEC
Ceramics: Base Directive	84/500/EEC
Elastomers: Nitrosamines in Teats and Soothers	93/11/EEC

The list of authorized substances in Directive 90/128/EEC and following amendments concerns monomers and most types of additives, including substances which constitute the means of polymerization. Colors and catalysts are excluded from the Community lists. All of the more important information's on the evaluation of substances can be found in the document entitled “Synoptic” which is to be distributed on the Internet under http://cpf.jrc.it/webpack/.

The legislation in force provides for two types of restrictions. The first, applying to all substances, provides that they may not be released alone or together with others in quantities greater than the overall migration limit, which is designed on the one hand to impart a certain inertness to material intended to come into contact with food so as to guarantee its purity and on the other hand to avoid setting a special migration limit for each substance.

The second type of restriction, which applies to isolated substances, provides that they must not migrate in quantities higher than a certain value fixed in accordance with the toxicological characteristics of each term. The SML value is generally calculated on the basis of the ADI or TDI laid down by the SCF for these substances. SMLs established in this way contain inbuilt safety margins in the range of 100 – 1000 relative to the NTEL and range typically from the low ppb level (µg/kg) for specific substances of toxicological concern such as acrylamide (10 ppb), butadiene (20 ppb), acrylonitrile (20 ppb), and others up to the lower ppm level (mg/kg) for less toxic principals such as bisphenol A (3 ppm), ethylenediamine (12 ppm) or 1-octene (15 ppm).

The European Commission Directive lists QM limits in cases where the migrant is not chemical stable enough in food simulants or may be lost during migration testing due to its volatility. A typical example is 2,2-bis(4-hydroxyphenyl)propane bis(2,3-epoxypropyl) ether (BADGE) which is listed in 90/128/EEC with both a SML value of 20 ppb and a QM value of 1 mg/kg polymer.

For new substances to be included in the community lists the industry has to submit a special request accompanied by a technical file containing a set of data which will enable the SCF to evaluate the risk associated with the use of that substance. These data were laid down by the SCF in the “Guidelines of the Scientific Committee for Food”.

Migration Measurements. Because of the variety and complexity of chemical components in polymers, the directive 82/711/EEC was adopted to establish the general rules for migration testing. As a consequence of the analytical difficulty of measuring migration into food, standardized measurement procedures have been developed which employ food-simulating liquids with properties very close to those of foods, as well as contact time and temperatures. The following simulants can be used:

Simulant A: distilled water
Simulant B: 3 % (w/v) acetic acid in water
Simulant C: 10 vol % ethanol in water
Simulant D: distilled olive oil

The first amendment to Council Directive 93/8/EEC made the standard conditions for migration testing more flexible by allowing a greater number of possible combinations of times and temperatures and the use of other simulants for the “fat test”. A second amendment, Directive 97/48/EEC, laid down the conditions of use of volatile solvents, e.g., isooctane and ethanol, as testing liquids in the “fat test”. It provides that these solvents may replace olive oil or other fat simulants (HB 307, sunflower oil, etc.) if the fat test is not applicable in the basic version for technical reasons or in routine checking. The migration of substances under these simulation conditions should not exceed the limits given in the positive list.

Directive 85/572/EEC includes a table of correlations between food groups and their food-simulating liquids. For some food groups the migration into Simulant D is too high and must be divided by the reduction factor specified in the table.

Directive 85/374/EEC should be mentioned because it affixes the responsibility of interaction problems to all who are involved in manufacture of packaged food (i.e., packaging and food producers or fillers). The producers of packaged food are responsible for problems (e.g., interactions) arising from the use of their product if they cannot demonstrate that the state-of-the-art in science and technology was considered at the time of production.

8.4.3. *United States*

The laws governing food packaging in the United States is the Federal Food, Drug, and Cosmetic act of 1958, as amended, and the Fair Packaging and Labeling Act. These regulations are specified in the Code of Federal Regulations (CFR). The CFR is organized under 50 titles. Of practical importance for packaging is Title 21, which contains general regulations for enforcement of the Federal Food, Drug, and Cosmetic Act and the Fair Packaging and Labeling Act (CFR 21, Part 1). Regulations for current manufacturing, processing or holding of human food (CFR 21, Part 110) and for additives in packaging materials (indirect food additives) can be found in the CFR 21, Parts 170 – 199 [152], [153].

Regulations for food additives are established by petitioning the FDA for permission to manufacture food-packaging material. The petition generally contains the following information:

1. Identity of the additive/polymer.
2. Use.
3. Intended technical effect.
4. Migration and analytical methodology.

The petition should provide sufficient information to estimate the daily intake of the additive, i.e., consumer exposure. From analyzed or estimated levels of an additive in food or food-simulating solvent, the concentration of the additive expected in the daily diet is calculated. An estimation of the exposure to an additive in the diet is determined by combining migration data from food simulants or actual foods with information on the use of packaging that may contain this additive.

The consumption factor (CF) is used to describe the fraction of the daily diet expected to contact specific packaging materials. The CF represents the ratio of the weight of all food contacting a specific packaging material to the weight of all food packed. These values were derived from information on the types of food consumed, the types of food contacting each packaging surface, the number of food-packaging units in each food-packaging category, the distribution of container sizes, and the ratio of the weight of food packaged to the weight of the package. The minimum CF used for exposure estimates involving low-consumption applications is 0.05. This value may, however, be modified as new packaging information is received.

Before migration levels can be combined with CF values to derive estimates of probable consumption, the nature of the food that is likely to contact the packaging material must be known. Migration into a fatty food simulant, for example, will be of little use in estimating probable exposure if the packaging material is used exclusively to package aqueous food. To account for the variable nature of the food contacting each packaging material, food-type distribution factors f_T have been calculated for each packaging material to reflect the fraction of all food contacting each material that is aqueous, acid, alcoholic, and fatty. The total dietary concentration is calculated as follows:

$$\text{Dietary Concentration} = \text{CF} \cdot \sum_{i=1}^{4} (M_i f_T) \qquad (10)$$

were M_i is the concentration of the migrant in the *i*th food-simulating solvent (aqueous, acidic, alcoholic, fatty) expressed in mg/kg (ppm). Simulant concentrations are equivalent to food concentrations if the simulant volume to exposed surface area ratio is 10 g/in^2 (under the assumption that 10 g of food is in contact with 1 in^2 of surface area).

The threshold value of regulation is 2000 times lower than the dietary concentration at which the vast majority of studied compounds are likely to cause noncarcinogenic toxic effects and 200 times lower than the chronic exposure level at which potent pesticides induce toxic effects. FDA believes that these safety margins, which are larger than the 100-fold safety factor that is typically used in applying animal experimentation data to human (21 CFR 170.22), support a conclusion that substances consumed in a dietary concentration at or below 0.5 μg/kg are not of concern.

Migration Measurements. As a consequence of the analytical difficulty of measuring migration into food, standardized measurement procedures have been developed which employ food-simulating liquids whose properties are very close to those of foods, as well as contacting time and temperatures. The following simulants can be used:

10 % ethanol (aqueous and acid foods),
10–50 % ethanol (low- and high-alcohol foods),
Edible oil (e.g., corn oil), HB307, or Migliol 812 (fatty foods).

8.4.4. *Japan*

Food Chemistry and Administration is executed under the Food Sanitation Law [154]. This law applies not only to food and additives, but to food apparatus and containers/packages such as kitchen utensils, tableware, bottles, cans, and wrapping paper; even toys and detergents. Standards and specifications for apparatus and containers/packages were established under “Specifications and Standards for Foods, Additives, etc., Announcement No. 370” including additional establishments and partial amendments. All apparatus and containers/packages which come into direct contact with foods are governed by regulation of the Food Sanitation Law. Briefly “apparatus” means articles used for manufacturing, processing, and otherwise handling foods, and “containers/packages” means articles used for wrapping and packaging foods for delivery. The sale of toxic or injurious apparatus or containers/packages is prohibited by law (Article 9).

The specifications for apparatus and containers/packages are mainly divided into three types:

1. Specifications applying generally to apparatus and containers/packages and their raw materials. These specifications cover those containing metals and colors. Those concerning metals are targeted at tin for plating, solder, and products including copper, lead, and antimony. The specifications concerning colors applies to all products. Any color used for apparatus and containers/packages must be one designated by the Minister of Health and Welfare under Article 6 of the law. However, this does not apply where no color dissolves or migrates into foods.
2. Specifications for apparatus and containers/packages applying to individual materials. The law specifies six materials which become targets of specifications for apparatus and containers/packages. They are glass, ceramics, enamel, synthetic resins, rubber, and metal. Paper and wood are not specified as target materials of specifications. However, products made of these two materials are subject to Article 9 of the law (see above).
3. Specifications for apparatus and containers/packages according to use. This uses include containers and packages which are pasteurized under pressure, or for nonalcoholic beverages; apparatus used for manufacturing ice candies and other similar products; food vending machines and containers for selling foods from vending machines; or transporting apparatus or container/packages of stock solutions kept in cup-filling type vending machines or in automatic preparing machines.

Migration Measurements. The specification includes material tests and elution tests. Material tests determine ingredients derived from the raw material used. Several types of materials are determined, such as metals (e.g., cadmium and lead) and volatile substances. Elution tests determine the amounts of substances that dissolve in solutions prepared under specific conditions. These tests determine various items such as residues on evaporation, heavy metals, and consumption of potassium permanganate.

The specifications for synthetic resins are divided into specifications that apply generally to all resins and specifications that apply specifically to individual resins. In both cases, material tests and elution tests are specified. The elution tests are performed with *n*-heptane, 20 % ethanol, water, and 4 % acetic acid and are evaluated by the residue on evaporation, expressed in ppm. The conditions for extraction are 60 min at 25 °C for *n*-heptane, and 30 min at 60 °C (90 °C for high-temperature use) for the other solvents.

9. Packaging and the Environment

Norbert Buchner

Packaging causes waste, which represents a major problem particularly in *urban* regions that lack disposal areas. The total amount of refuse from an average household in an economic system with high packaging rates has proved to be lower than from the equivalent household in a less developed system (see Section Functions and Effects.). However, the composition of the waste differs, and the former are more dependent on public refuse systems. In the Federal Republic of Germany, for instances, the amount of solid household waste resulting from packaging (approximately 8×10^6 t/a) represents about 30 % of the total household refuse (26×10^6 t/a). However, with respect to the total solid waste of 5×10^8 t/a, this amounts to only ca. 1.6 %. Disposable packages for beverages, whose refuse of 4×10^5 t/a represents ca. 1.5 % of total household waste, are particular objects of attention. Many of the conventional measures designed to reduce packaging costs also lead to *refuse reduction*. In the Federal Republic of Germany the fraction of packaging material in the gross national product dropped from ca. 2 % to 1.5 % within three decades.

Within the field of *waste recycling*, a parallel exists between material and energy recycling. Very high, but still increasing, rates of recycling occur with glass (the Netherlands leads with almost 50 %, compared to the Federal Republic of Germany which recycles around 40 %) [120]. When compared with the expenditure for new glass, this can lead in an ideal case to an energy saving of almost 25 % in manufacturing. In the Federal Republic of Germany, ca. 40 % of tin cans are recycled, amounting to a theoretical energy saving of 60 % in comparison with new cans. In the United States, where aluminum recycling is particularly attractive due to the widespread use of aluminum cans, a return system has been built up that allows a possible energy saving of over 90 %. A high percentage of packaging papers, cardboard, and corrugated cardboard is manufactured from secondary fibers (see Sections Cardboard, Corrugated Cardboard, Coated Paper and Cardboard); however, these originate to a low degree in the packaging sector.

Methods of *refuse disposal* include dumps, composting, incineration, and pyrolysis. With correct disposal or composting of packaging materials, danger to the environment (soil, water, air) can be ruled out. Thermal methods of disposal (refuse power stations, pyrolysis) are increasingly regarded as, in effect, energy-recycling systems, which can also reduce the amount of deposited waste by 90 – 95 %. When paper and cardboard are incinerated in refuse power stations, up to 65 % of the expenditure of energy can be recycled, with plastics more than 50 % of the primary energy (fuel value and production energy) is regained [122]. Refuse power stations are today able to meet more stringent exhaust gas regulations than conventional heating power stations [121].

1. Introduction

Formaldehyde occurs in nature and is formed from organic material by photochemical processes in the atmosphere as long as life continues on earth. Formaldehyde is an important metabolic product in plants and animals (including humans), where it occurs in low but measurable concentrations. It has a pungent odor and is an irritant to the eye, nose, and throat even at a low concentration; the threshold concentration for odor detection is 0.05 – 1 ppm. However, formaldehyde does not cause any chronic damage to human health. Formaldehyde is also formed when organic material is incompletely combusted; therefore, formaldehyde is found in combustion gases from, for example, automotive vehicles, heating plants, gas-fired boilers, and even in cigarette smoke. Formaldehyde is an important industrial chemical and is employed in the manufacture of many industrial products and consumer articles. More than 50 branches of industry now use formaldehyde, mainly in the form of aqueous solutions and formaldehyde-containing resins. In 1995, the demand for formaldehyde in the three major markets – Northern America, Western Europe, Japan – was 4.1×10^6 t/a [1].

History. Formaldehyde was first synthesized in 1859, when BUTLEROV hydrolyzed methylene acetate and noted the characteristic odor of the resulting solution. In 1867, HOFMANN conclusively identified formaldehyde, which he prepared by passing methanol vapor and air over a heated platinum spiral. This method, but

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a11_619

with other catalysts, still constitutes the principal method of manufacture. The preparation of pure formaldehyde was described later by KEKULÉ in 1882.

Industrial production of formaldehyde became possible in 1882, when TOLLENS discovered a method of regulating the methanol vapor : air ratio and affecting the yield of the reaction. In 1886 LOEW replaced the platinum spiral catalyst by a more efficient copper gauze. The German firm, Mercklin und Lösekann, started to manufacture and market formaldehyde on a commercial scale in 1889. Another German firm, Hugo Blank, patented the first use of a silver catalyst in 1910.

Industrial development continued from 1900 to 1905, when plant sizes, flow rates, yields, and efficiency were increased. In 1905, Badische Anilin & Soda-Fabrik started to manufacture formaldehyde by a continuous process employing a crystalline silver catalyst. Formaldehyde output was 30 kg/d in the form of an aqueous 30 wt % solution.

The methanol required for the production of formaldehyde was initially obtained from the timber industry by carbonizing wood. The development of the high-pressure synthesis of methanol by Badische Anilin & Soda-Fabrik in 1925 allowed the production of formaldehyde on a true industrial scale.

2. Physical Properties

2.1. Monomeric Formaldehyde

Formaldehyde [*50-00-0*], CH_2O, M_r 30.03, is a colorless gas at ambient temperature that has a pungent, suffocating odor and an irritant action on the eyes and skin.

Formaldehyde liquefies at −19.2 °C, the density of the liquid being 0.8153 g/cm^3 at −20 °C and 0.9172 g/cm^3 at −80 °C. It solidifies at −118 °C to give a white paste. The liquid and gas polymerize readily at low and ordinary temperatures up to 80 °C. Pure formaldehyde gas does not polymerize between 80 and 100 °C and behaves as an ideal gas. For the UV absorption spectra of formaldehyde, see [2]. Structural information about the formaldehyde molecule is provided by its fluorescence [3], IR [4], RAMAN [5], and microwave spectra [6]. Following are some of the thermodynamic properties of gaseous formaldehyde:

Heat of formation at 25 °C	−115.9 ± 6.3 kJ/mol
Gibbs energy at 25 °C	−109.9 kJ/mol
Entropy at 25 °C	218.8 ± 0.4 kJmol^{-1} K^{-1}
Heat of combustion at 25 °C	−561.5 kJ/mol
Heat of vaporization at −19.2 °C	23.32 kJ/mol
Specific heat capacity at 25 °C, c_p	35.425 Jmol^{-1} K^{-1}
Heat of solution at 23 °C	
in water	−62 kJ/mol
in methanol	−62.8 kJ/mol
in 1-propanol	−59.5 kJ/mol
in 1-butanol	−62.4 kJ/mol
Cubic expansion coefficient	2.83×10^{-3} K^{-1}
Specific magnetic susceptibility	-0.62×10^6
Vapor density relative to air	1.04

The vapor pressure p of liquid formaldehyde has been measured from −109.4 to −22.3 °C [7] and can be calculated for a given temperature T (K) from the following equation:

$$p\,(\mathrm{kPa}) = 10^{[5.0233-(1429/T)+1.75\log T-0.0063T]}$$

Polymerization in either the gaseous or the liquid state is influenced by wall effects, pressure, traces of humidity, and small quantities of formic acid. Formaldehyde gas obtained by vaporization of paraformaldehyde or more highly polymerized α-polyoxymethylenes, which is ca. 90 – 100 % pure, must be stored at 100 – 150 °C to prevent polymerization. Chemical decomposition is insignificant below 400 °C.

Formaldehyde gas is flammable, its ignition temperature is 430 °C [8]; mixtures with air are explosive. At ca. 20 °C the lower and upper explosive limits of formaldehyde are ca. 7 and 72 vol % (87 and 910 g/m^3), respectively [9]. Flammability is particularly high at a formaldehyde concentration of 65 – 70 vol %.

At a low temperature, liquid formaldehyde is miscible in all proportions with nonpolar solvents such as toluene, ether, chloroform, or ethyl acetate. However, solubility decreases with increasing temperature and at room temperature polymerization and volatilization occur, leaving only a small amount of dissolved gas. Solutions of liquid formaldehyde in acetaldehyde behave as ideal solutions [10]. Liquid formaldehyde is slightly miscible with petroleum ether and *p*-cymene [11].

Polar solvents, such as alcohols, amines or acids, either catalyze the polymerization of formaldehyde or react with it to form methylol compounds or methylene derivatives.

2.2. Aqueous Solutions

At room temperature, pure aqueous solutions contain formaldehyde in the form of methylene glycol $HOCH_2OH$ [*463-57-0*] and its oligomers, namely the low molecular mass poly(oxymethylene) glycols with the following structure

$$HO(CH_2O)_nH \ (n = 1-8)$$

Monomeric, physically dissolved formaldehyde is only present in low concentrations of up to 0.1 wt %. The polymerization equilibrium

$$HOCH_2OH + n\,CH_2O \rightleftharpoons HO(CH_2O)_{n+1}-H$$

is catalyzed by acids and is shifted toward the right at lower temperature and/or higher formaldehyde concentrations, and toward the left if the system is heated and/or diluted [12], [13] (see also Section 11.1).

Dissolution of formaldehyde in water is exothermic, the heat of solution (− 62 kJ/mol) being virtually independent of the solution concentration [14]. Clear, colorless solutions of formaldehyde in water can exist at a formaldehyde concentration of up to 95 wt %, but the temperature must be raised to 120 °C to obtain the highest concentrations. Concentrated aqueous solutions containing more than 30 wt % formaldehyde become cloudy on storage at room temperature, because larger poly(oxymethylene) glycols ($n \geq 8$) are formed which then precipitate out (the higher the molecular mass of the polymers, the lower is their solubility).

Table 1. Calculated distribution of oligomers of methylene glycol, $HO(CH_2O)_nH$, in an aqueous 40 wt % formaldehyde solution at 35 °C [12]

n	Proportion, %	n	Proportion, %
1	26.80	7	3.89
2	19.36	8	2.50
3	16.38	9	1.59
4	12.33	10	0.99
5	8.70	> 10	1.58
6	5.89		

Equilibrium constants have been determined for the physical dissolution of formaldehyde in water and for the reaction of formaldehyde to give methylene glycol and its oligomers [12]. These parameters can be combined with other data to calculate the approximate equilibria at any temperature from 0 to 150 °C and at a formaldehyde concentration of up to 60 wt % [13]. Table 1 gives the calculated oligomer distribution in an aqueous 40 wt % solution of formaldehyde.

A kinetic study of the formation of methylene glycol from dissolved formaldehyde and water shows that the reverse reaction is 5×10^3 to 6×10^3 times slower than the forward reaction [15], and that it increases greatly with the acidity of the solution. This means that the distribution of the higher mass oligomers ($n > 3$) does not change rapidly when the temperature is increased or the solution is diluted; the methylene glycol content then rises at the expense of the smaller oligomers ($n = 2$ or 3). In aqueous solutions containing ≤ 2 wt % formaldehyde, formaldehyde is entirely monomeric.

Methylene glycol can be determined by the bisulfite method [16] or by measuring the partial pressure of formaldehyde [17]. Molecular masses and monomer contents can be determined by NMR spectroscopy [13], [18].

The approximate amount of monomeric formaldehyde present as formaldehyde hemiformal and methylene glycol in aqueous solutions containing formaldehyde and methanol, can be calculated from data at 25 – 80 °C [19] by using the following equation:

$$\text{Monomer (mol\%)} = 100 - 12.3\sqrt{F} + (1.44 - 0.0164F)\,M$$

where F is the formaldehyde concentration (7 – 55 wt %) and M is the methanol concentration (0 – 14 wt %).

The partial pressure p_F of formaldehyde above aqueous solutions has been measured by Ledbury and Blair and computed by Walker and Lacy [20]. The parameter p_F for solutions in which F is in the range 0 – 40 wt % can be calculated with a relative error of 5 – 10 % in the temperature range $T = 273 - 353$ K by using the following equation :

$$p_F\,(\text{kPa}) = 0.1333F e^{-F^{\alpha}(a_0 + a_1/T + a_2/T^2)}$$

$$\alpha = 0.08760 \pm 0.00950$$

$$a_0 = -12.0127 \pm 0.0550$$

$$a_1 = 3451.72 \pm 17.14$$

$$a_2 = 248257.3 \pm 5296.8$$

Results of such calculations are given in Table 2 and agree well with the measured values.

Table 3 gives the partial pressures and concentrations of formaldehyde in the liquid and

Table 2. Partial pressure p_F of formaldehyde (kPa) above aqueous formaldehyde solutions

49.8	34.0	24.1

Aqueous Formaldehyde – Methanol Solutions. Technical-grade formaldehyde solutions contain a small amount of methanol as a result of the incomplete methanol conversion during formaldehyde production. The amount of methanol present depends on the production process employed. The presence of methanol is often desirable in aqueous solutions containing more than 30 wt % formaldehyde because it inhibits the formation of insoluble, higher mass polymers. Methanol concentrations of up to 16 wt % stabilize the formaldehyde.

The approximate *density* ϱ (in grams per cubic centimeter) of aqueous formaldehyde solutions containing up to 13 wt % methanol at a temperature of 10 – 70 °C can be calculated by using the following equation [22]:

$$\varrho = a + 0.0030\,(F - b) - 0.0025\,(M - c) - 10^4\,[0.055\,(F - 30) + 5.4]\,(t - 20)$$

where

F = formaldehyde concentration in wt %
M = methanol concentration in wt %
t = temperature in °C
a, b, and c = constants

The following values can be assumed when F is in the range 0 – 48: $a = 1.092$, $b = 30$, and $c = 0$. The corresponding values in the range $F = 48 - 55$ are $a = 1.151$, $b = 50.15$, and $c = 1.61$.

The *boiling points* of pure aqueous solutions containing up to 55 wt % formaldehyde are between 99 and 100 °C at atmospheric pressure [23]. In dilute aqueous solutions, formaldehyde lowers the freezing point of water. If solutions containing more than 25 wt % formaldehyde are cooled, polymer precipitates out before the freezing point is reached. According to Natta [22], the approximate *refractive index* n_D^{18} of aqueous 30 – 50 wt % formaldehyde solutions containing up to 15 wt % methanol can be calculated from the following equation:

$$n_D^{18} = 1.3295 + 0.00125F + 0.000113M$$

where F and M are wt % concentrations of formaldehyde and methanol, respectively.

In close agreement with measurements of commercial solutions, the *dynamic viscosity* η

of aqueous formaldehyde – methanol solutions may be expressed by the following equation [24]:

$$\eta\,(\mathrm{mPa{\cdot}s}) = 1.28 + 0.039F + 0.05M - 0.024t$$

This equation applies to solutions containing 30 – 50 wt % formaldehyde and 0 – 12 wt % methanol at a temperature t of 25 – 40 °C.

Detailed studies on chemical reactions, vapor–liquid equilibria and caloric properties of systems containing formaldehyde, water, and methanol are available [216–226].

3. Chemical Properties

Formaldehyde is one of the most reactive organic compounds known and, thus, differs greatly from its higher homologues and aliphatic ketones [25], [26]. Only the most important of its wide variety of chemical reactions are treated in this article; others are described in [27]. For a general discussion of the chemical properties of saturated aldehydes, see → Aldehydes, Aliphatic and Araliphatic, Chap. 2.

Decomposition. At 150 °C, formaldehyde undergoes heterogeneous decomposition to form mainly methanol and CO_2 [28]. Above 350 °C, however, it tends to decompose into CO and H_2 [29]. Metals such as platinum [30], copper [31], chromium, and aluminum [32] catalyze the formation of methanol, methyl formate, formic acid, CO_2, and methane.

Polymerization. Anhydrous monomeric formaldehyde cannot be handled commercially. Gaseous formaldehyde polymerizes slowly at temperatures below 100 °C, polymerization being accelerated by traces of polar impurities such as acids, alkalis, or water (see paraformaldehyde, Section 11.1). Thus, in the presence of steam and traces of other polar compounds, the gas is stable at ca. 20 °C only at a pressure of 0.25 – 0.4 kPa, or at a concentration of up to ca. 0.4 vol % at ca. 20 °C and atmospheric pressure.

Monomeric formaldehyde forms a hydrate with water; this hydrate reacts with further formaldehyde to form polyoxymethylenes (see Section 2.2). Methanol or other stabilizers, such as guanamines [33] or alkylenebis(melamines) [34], are generally added to commercial aqueous formaldehyde solutions (37 – 55 wt %) to inhibit polymerization.

Reduction and Oxidation. Formaldehyde is readily reduced to methanol with hydrogen over a nickel catalyst [27], [35]. For example, formaldehyde is oxidized by nitric acid, potassium permanganate, potassium dichromate, or oxygen to give formic acid or CO_2 and water [27], [36].

In the presence of strong alkalis [37] or when heated in the presence of acids [38], formaldehyde undergoes a Cannizzaro reaction with formation of methanol and formic acid [39]. In the presence of aluminum or magnesium methylate, paraformaldehyde reacts to form methyl formate (Tishchenko reaction) [27].

Addition Reactions. The formation of sparingly water-soluble sodium formaldehyde bisulfite is an important addition reaction of formaldehyde [40]. Hydrocyanic acid reacts with formaldehyde to give glycolonitrile [*107-16-4*] [27]. Formaldehyde undergoes an acid-catalyzed Prins reaction in which it forms α-hydroxymethylated adducts with olefins [24]. Acetylene undergoes a Reppe addition reaction with formaldehyde [41] to form 2-butyne-1,4-diol [*110-65-6*]. Strong alkalis or calcium hydroxide convert formaldehyde to a mixture of sugars, in particular hexoses, by a multiple aldol condensation which probably involves a glycolaldehyde intermediate [42], [43]. Mixed aldols are formed with other aldehydes; the product depends on the reaction conditions. Acetaldehyde, for example, reacts with formaldehyde to give pentaerythritol, $C(CH_2OH)_4$ [*115-77-5*] (→ Alcohols, Polyhydric, Chap. 4.).

Condensation Reactions. Important condensation reactions are the reaction of formaldehyde with amino groups to give Schiff's bases, as well as the Mannich reaction [27]. Amines react with formaldehyde and hydrogen to give methylamines. Formaldehyde reacts with ammonia to give hexamethylenetetramine, and with ammonium chloride to give monomethylamine, dimethylamine, or trimethylamine and formic acid, depending on the reaction conditions [44]. Reaction of formaldehyde with diketones and ammonia yields imidazoles [45].

Formaldehyde reacts with many compounds to produce methylol ($-CH_2OH$) derivatives. It reacts with phenol to give methylolphenol, with urea to give mono-, di-, and trimethylolurea, with melamine to give methylolmelamines, and with organometallic compounds to give metal-substituted methylol compounds [27].

Aromatic compounds such as benzene, aniline, and toluidine combine with formaldehyde to produce the corresponding diphenylmethanes. In the presence of hydrochloric acid and formaldehyde, benzene is chloromethylated to form benzyl chloride [*100-44-7*] [46]. The possible formation of bis(chloromethyl)ether [*542-88-1*] from formaldehyde and hydrochloric acid and the toxicity of this compound are reported elsewhere (→ Ethers, Aliphatic).

Formaldehyde reacts with hydroxylamine, hydrazines, or semicarbazide to produce formaldehyde oxime (which is spontaneously converted to triformoxime), the corresponding hydrazones, and semicarbazone, respectively. Double bonds are also produced when formaldehyde is reacted with malonates or with primary aldehydes or ketones possessing a CH_2 group adjacent to the carbonyl group.

Resin Formation. Formaldehyde condenses with urea, melamine, urethanes, cyanamide, aromatic sulfonamides and amines, and phenols to give a wide range of resins (→ Amino Resins; → Phenolic Resins; → Resins, Synthetic).

4. Production

Formaldehyde is produced industrially from methanol [*67-56-1*] by the following three processes:

1) Partial oxidation and dehydrogenation with air in the presence of silver crystals, steam, and excess methanol at 680 – 720 °C (BASF process, methanol conversion = 97 – 98 %).
2) Partial oxidation and dehydrogenation with air in the presence of crystalline silver or silver gauze, steam, and excess methanol at 600 – 650 °C [47] (primary conversion of methanol = 77 – 87 %). The conversion is completed by distilling the product and recycling the unreacted methanol.
3) Oxidation only with excess air in the presence of a modified iron – molybdenum – vanadium oxide catalyst at 250 – 400 °C (methanol conversion = 98 – 99 %).

Processes for converting propane, butane [48], ethylene, propylene, butylene [49], or ethers (e.g., dimethyl ether) [50] into formaldehyde are not of major industrial significance for economic reasons. Processes that employ partial hydrogenation of CO [51] or oxidation of methane [52] do not compete with methanol conversion processes because of the lower yields of the former processes.

The specifications of the methanol, used for formaldehyde production according to processes 1 – 3 are listed in Table 4. However, crude aqueous methanol obtained by high- [54], medium-, or low-pressure [55] synthesis can also be used for process 1. This methanol contains low concentrations of inorganic impurities and limited amounts of other organic compounds. The methanol must be first subjected to purification processes and preliminary distillation to remove low-boiling components.

Table 4. Specifications of commercial methanol (grade AA) used for the production of formaldehyde [53]

Parameter	Specification
Methanol content	> 99.85 wt %
Relative density, d_4^{20}	0.7928 g/cm^3
Maximum boiling point range	1 °C
Acetone and acetaldehyde content	< 0.003 wt %
Ethanol content	< 0.001 wt %
Volatile iron content	< 2 µg/L
Sulfur content	< 0.0001 wt %
Chlorine content	< 0.0001 wt %
Water content	< 0.15 wt %
pH	7.0
$KMnO_4$ test, minimum decolorization time	30 min

4.1. Silver Catalyst Processes

The silver catalyst processes for converting methanol to formaldehyde are generally carried out at atmospheric pressure and at 600 – 720 °C. The reaction temperature depends on the excess of methanol in the methanol – air mixture. The composition of the mixture must lie outside the explosive limits. The amount of air that is used is also determined by the catalytic quality of the silver surface. The following main reactions occur during the conversion of methanol to formaldehyde:

$$CH_3OH \rightleftharpoons CH_2O + H_2 \quad \Delta H = +84\ \text{kJ/mol} \quad (1)$$

$$H_2 + 1/2\ O_2 \rightarrow H_2O \quad \Delta H = -243\ \text{kJ/mol} \quad (2)$$

$$CH_3OH + 1/2\ O_2 \rightarrow CH_2O + H_2O \quad \Delta H = -159\ \text{kJ/mol} \quad (3)$$

The extent to which each of these three reactions occurs, depends on the process data.

Byproducts are also formed in the following secondary reactions:

$$CH_2O \rightarrow CO + H_2 \quad \Delta H = +12.5\ \text{kJ/mol} \quad (4)$$

$$CH_3OH + 3/2\ O_2 \rightarrow CO_2 + 2\ H_2O \quad \Delta H = -674\ \text{kJ/mol} \quad (5)$$

$$CH_2O + O_2 \rightarrow CO_2 + H_2O \quad \Delta H = -519\ \text{kJ/mol} \quad (6)$$

Other important byproducts are methyl formate, methane, and formic acid.

The endothermic dehydrogenation reaction (1) is highly temperature-dependent, conversion increasing from 50 % at 400 °C to 90 % at 500 °C and to 99 % at 700 °C. The temperature dependence of the equilibrium constant for this reaction K_p is given by

$$\log K_p = (4600/T) - 6.470$$

For detailed thermodynamic data of reactions (1) – (6) see [56]. Kinetic studies with silver on a carrier show that reaction (1) is a first-order reaction [57]. Therefore, the rate of formaldehyde formation is a function of the available oxygen concentration and the oxygen residence time on the catalyst surface:

$$\frac{dc_F}{dt} = kc_o$$

where

c_F = formaldehyde concentration
c_O = oxygen concentration
k = rate constant
t = time

A complete reaction mechanism for the conversion of methanol to formaldehyde over a silver catalyst has not yet been proposed. However, some authors postulate that a change in mechanism occurs at ca. 650 °C [58]. New insight into the reaction mechanism is available from spectroscopic investigations [227–229], which demonstrate the influence of different atomic oxygen species on reaction pathway and selectivity. The synthesis of formaldehyde over a silver catalyst is carried out under strictly adiabatic conditions. Temperature measurements both above and in the silver layer show that sites still containing methanol are separated from sites already containing predominantly formaldehyde by only a few millimeters.

The oxygen in the process air is shared between the exothermic reactions, primarily reaction (2) and, to a lesser extent depending on the process used, the secondary reactions (5) and (6). Thus, the amount of process air controls the desired reaction temperature and the extent to which the endothermic reactions (1) and (4) occur.

Another important factor affecting the yield of formaldehyde and the conversion of methanol, besides the catalyst temperature, is the addition of inert materials to the reactants. Water is added to spent methanol – water-evaporated feed mixtures, and nitrogen is added to air and air – off-gas mixtures, which are recycled to dilute the methanol – oxygen reaction mixture. The throughput per unit of catalyst area provides another way of improving the yield and affecting side reactions. These two methods of process control are discussed in [59].

The theoretical yield of formaldehyde obtained from Reactions (1) – (6) can be calculated from actual composition of the plant off-gas by using the following equation:

$$\text{Yield (mol\%)} = 100\left[+r + \frac{(\%CO_2)+(\%CO)}{0.528(\%N_2)+(\%H_2)-3(\%CO_2)-2(\%CO)}\right]^{-1}$$

Percentages signify concentrations in vol % and r is the ratio of moles of unreacted methanol to moles of formaldehyde produced [60]. The equation takes into account the hydrogen and oxygen balance and the formation of byproducts.

4.1.1. Complete Conversion of Methanol (BASF Process)

The BASF process for the complete conversion of methanol to formaldehyde is shown schematically in Figure 1 [61]. A mixture of methanol

and water is fed into the evaporating column. Fresh process air and, if necessary, recycled off-gas from the last stage of the absorption column enter the column separately [60]. A gaseous mixture of methanol in air is thus formed in which the inert gas content (nitrogen, water, and CO_2) exceeds the upper explosive limit. A ratio of 60 parts of methanol to 40 parts of water with or without inert gases is desired. The packed evaporator constitutes part of the stripping cycle. The heat required to evaporate the methanol and water is provided by a heat exchanger, which is linked to the first absorption stage of the absorption column [62]. After passing through a demister, the gaseous mixture is superheated with steam and fed to the reactor, where it flows through a 25 – 30 mm thick bed of silver crystals. The crystals have a defined range of particle sizes [63] and rest on a perforated tray, which is covered with a fine corrugated gauze, thus permitting optimum reaction at the surface. The bed is positioned immediately above a water boiler (cooler), which produces superheated steam and simultaneously cools the hot reaction gases to a temperature of 150 °C corresponding to that of the pressurized steam (0.5 MPa). The almost dry gas from the gas cooler passes to the first stage of a four-stage packed absorption column, where the gas is cooled and condensed. Formaldehyde is eluted countercurrent to water or to the circulating formaldehyde solutions whose concentrations increase from stage to stage.

The product circulating in the first stage may contain 50 wt % formaldehyde if the temperature of the gas leaving this stage is kept at ca. 75 °C; this temperature provides sufficient evaporation energy for the feed stream in the heat exchanger. The final product contains 40 – 55 wt % formaldehyde, as desired, with an average of 1.3 wt % methanol and 0.01 wt % formic acid. The yield of the formaldehyde process is 89.5 – 90.5 mol %. Some of the off-gas is removed at the end of the fourth stage of the column [60] and is recycled due to its extremely low formaldehyde content (Fig. 1, route indicated by dashed-dotted lines). The residual off-gas is fed to a steam generator, where it is combusted [64] (net calorific value = 1970 kJ/m^3). Prior to combustion the gas contains ca. 4.8 vol % CO_2, 0.3 vol % CO, and 18.0 vol % H_2 as well as nitrogen, water, methanol, and formaldehyde. The combusted off-gas contains no environmentally harmful substances. The total steam equivalent of the process is 3 t per ton of 100 wt % formaldehyde.

a) Evaporator; b) Blower; c) Reactor; d) Boiler; e) Heat exchanger; f) Absorption column; g) Steam generator; h) Cooler; i) Superheater
Recycling schemes : –·–·– off-gas, – – – – formaldehyde solution.

In an alternative procedure to the off-gas recycling process (Fig. 1, dashed lines) the formaldehyde solution from the third or fourth stage of the absorption tower is recycled to the evaporator; a certain amount of steam is used in the evaporation cycle. The resulting vapor is combined with the feed stream to the reactor to obtain an optimal methanol : water ratio [65]. In this case, the temperature of the second stage of the absorption column is ca. 65 °C.

The yields of the two processes are similar and depend on the formaldehyde content of the recycled streams.

The average life time of a catalyst bed depends on impurities such as inorganic materials in the air and methanol feed; poisoning effects caused by some impurities are partially reversible within a few days. The life time of the catalyst is also adversely affected by long exposure to excessively high reaction temperatures and high throughput rates because the silver crystals then become matted and cause an increase in pressure across the catalyst bed. This effect is irreversible and the catalyst bed must be changed after three to four months. The catalyst is regenerated electrolytically.

Since formaldehyde solutions corrode carbon steel, all parts of the manufacturing equipment that are exposed to formaldehyde solutions must be made of a corrosion-resistant alloy, e.g., certain types of stainless steel. Furthermore, tubes that convey water or gases must be made of alloys to protect the silver catalyst against metal poisoning.

If the throughput and reaction temperature have been optimized, the capacity of a formaldehyde plant increases in proportion to the diameter of the reactor. The largest known reactor appears to be that of BASF in the Federal Republic of Germany; it has an overall diameter of 3.2 m and a production capacity of 72 000 t/a (calculated as 100 wt % formaldehyde).

4.1.2. Incomplete Conversion and Distillative Recovery of Methanol

Formaldehyde can be produced by partial oxidation and distillative recovery of methanol. This process is used in numerous companies (e.g., ICI, Borden, and Degussa) [66]. As shown in Figure 2, a feed mixture of pure methanol vapor and freshly blown-in air is generated in an evaporator. The resulting vapor is combined with steam, subjected to indirect superheating, and then fed into the reactor. The reaction mixture contains excess methanol and steam and is very similar to that used in the BASF process (cf. Section 4.1.1). The vapor passes through a shallow catalyst bed of silver crystals or through layers of silver gauze. Conversion is incomplete and the reaction takes place at 590 – 650 °C, undesirable secondary reactions being suppressed by this comparatively low temperature. Immediately after leaving the catalyst bed, the reaction gases are cooled indirectly with water, thereby generating steam. The remaining heat of reaction is then removed from the gas in a cooler and is fed to the bottom of a formaldehyde absorption column. In the water-cooled section of the column, the bulk of the methanol, water, and formaldehyde separate out. At the top of the column, all the condensable portions of the remaining formaldehyde and methanol are washed out of the tail gas by countercurrent contact with process water. A 42 wt % formaldehyde solution from the bottom of the absorption column is fed to a distillation column equipped with a steam-based heat exchanger and a reflux condenser. Methanol is recovered at the top of the column and is recycled to the bottom of the evaporator. A product containing up to 55 wt % formaldehyde and less than 1 wt % methanol is taken from the bottom of the distillation column and cooled. The formaldehyde solution is then usually fed into an anion-exchange unit to reduce its formic acid content to the specified level of less than 50 mg/kg.

If 50 – 55 wt % formaldehyde and no more than 1.5 wt % methanol are required in the product, steam addition is restricted and the process employs a larger excess of methanol. The ratio of distilled recycled methanol to fresh methanol then lies in the range 0.25 – 0.5. If a dilute product containing 40 – 44 wt % formaldehyde is desired, the energy-intensive distillation of methanol can be reduced, leading to savings in steam and power as well as reductions in capital cost. The off-gas from the absorption column has a similar composition to that described for the BASF process (in Section 4.1.1). The off-gas is either released into the atmosphere or is combusted to generate steam, thus avoiding environmental problems caused by residual formaldehyde. Alternatively, the tail gas from the top of the absorber can be recycled to the reactor. This inert gas, with additional steam, can reduce the excess methanol needed in the reactor feed, consequently providing a more concentrated product with less expenditure on distillation. The yield of the process is 91 – 92 mol %.

Process variations to increase the incomplete conversion of methanol employ two-stage oxidation systems [67]. The methanol is first partly

converted to formaldehyde, using a silver catalyst at a comparatively low temperature (e.g., 600 °C). The reaction gases are subsequently cooled and excess air is added to convert the remaining methanol in a second stage employing either a metal oxide (cf. Section 4.2) or a further silver bed as a catalyst.

Formaldehyde solutions in methanol with a relatively low water content can be produced directly by methanol oxidation and absorption in methanol [68]. Anhydrous alcoholic formaldehyde solutions or alcoholic formaldehyde solutions with a low water content can be obtained by mixing a highly concentrated formaldehyde solution with the alcohol (ROH) and distilling off an alcohol – water mixture with a low formaldehyde content. The formaldehyde occurs in the desired solutions in the form of the hemiacetals $RO(CH_2O)_nH$.

4.2. Formox Process

In the Formox process, a metal oxide (e.g., iron, molybdenum, or vanadium oxide) is used as a catalyst for the conversion of methanol to formaldehyde. Many such processes have been patented since 1921 [69]. Usually, the oxide mixture has an Mo : Fe atomic ratio of 1.5 – 2.0, small amounts of V_2O_5, CuO, Cr_2O_3, CoO, and P_2O_5 are also present [70]. Special conditions are prescribed for both the process and the activation of the catalyst [71]. The Formox process has been described as a two-step oxidation reaction in the gaseous state (g) which involves an oxidized (K_{OX}) and a reduced (K_{red}) catalyst [72]:

$$CH_3OH_{(g)} + K_{OX} \rightarrow CH_2O_{(g)} + H_2O_{(g)} + K_{red}$$

$$K_{red} + 1/2\ O_{2(g)} \rightarrow K_{OX}\ \Delta H = -159\ \text{kJ/mol}$$

$$CH_2O + 1/2\ O_2 \rightleftharpoons CO + H_2O\ \Delta H = -215\ \text{kJ/mol}$$

In the temperature range 270 – 400 °C, conversion at atmospheric pressure is virtually complete. However, conversion is temperature-dependent because at >470 °C the following side reaction increases considerably:

$$CH_2O + 1/2\ O_2 \rightleftharpoons CO + H_2O\ \Delta H = -215\ \text{kJ/mol}$$

The methanol oxidation is inhibited by water vapor. A kinetic study describes the rate of reaction to formaldehyde by a power law kinetic rate expression of the form [230]

$$r = kP^x_{CH_3OH} P^y_{O_2} P^z_{H_2O}$$

where $x = 0.94 \pm 0.06$; $y = 0.10 \pm 0{,}05$ and $z = -0.45 \pm 0.07$. The rate is independent of the formaldehyde partial pressure. The measured activation energy is 98 ± 6 kJ/mol.

As shown in Figure 3, the methanol feed is passed to a steam-heated evaporator. Freshly blown-in air and recycled off-gas from the absorption tower are mixed and, if necessary, preheated by means of the product stream in a heat exchanger before being fed into the evaporator. The gaseous feed passes through catalyst-filled tubes in a heat-exchanging reactor. A typical reactor for this process has a shell with a diameter of ca. 2.5 m that contains tubes only 1.0 – 1.5 m

in length. A high-boiling heat-transfer oil circulates outside the tubes and removes the heat of reaction from the catalyst in the tubes. The process employs excess air and the temperature is controlled isothermally to a value of ca. 340 °C; steam is simultaneously generated in a boiler. The air – methanol feed must be a flammable mixture, but if the oxygen content is reduced to ca. 10 mol % by partially replacing air with tail gas from the absorption tower, the methanol content in the feed can be increased without forming an explosive mixture [73]. After leaving the reactor, the gases are cooled to 110 °C in a heat-exchange unit and are passed to the bottom of an absorber column. The formaldehyde concentration is regulated by controlling the amount of process water added at the top of the column. The product is removed from the water-cooled circulation system at the bottom of the absorption column and is fed through an anion-exchange unit to reduce the formic acid content. The final product contains up to 55 wt % formaldehyde and 0.5 – 1.5 wt % methanol. The resultant methanol conversion ranges from 95 – 99 mol % and depends on the selectivity, activity, and spot temperature of the catalyst, the latter being influenced by the heat transfer rate and the throughput rate. The overall plant yield is 88 – 91 mol %.

Well-known processes using the Formox method have been developed by Perstorp/Reichhold (Sweden, United States, Great Britain) [74], [75], Lummus (United States) [76], Montecatini (Italy) [77], and Hiag/Lurgi (Austria) [78].

The tail gas does not burn by itself because it consists essentially of N_2, O_2, and CO_2 with a few percent of combustible components such as dimethyl ether, carbon monoxide, methanol, and formaldehyde. Combustion of Formox tail gas for the purpose of generating steam is not economically justifiable [79]. Two alternative methods of reducing atmospheric emission have been developed. The off-gas can be burned either with additional fuel at a temperature of 700 – 900 °C or in a catalytic incinerator at 450 – 550 °C. However, the latter system employs a heat exchanger and is only thermally self-sufficient if supplementary fuel for start-up is provided and if an abnormal ratio of oxygen : combustible components is used [80].

4.3. Comparison of Process Economics

Considering the economic aspects of the three formaldehyde processes in practice, it becomes obvious that the size of the plant and the cost of methanol are of great importance. Generally, the Formox process proves to be advantageous regarding the attainable formaldehyde yield. However, in comparison with the silver process this process demands a larger plant and higher investment costs. For the purpose of a cost comparison, a study was undertaken based on the cost of methanol being $ 200 /t and a plant production capacity of 20,000 t/a of 37 % formaldehyde (calculated 100 %) [1]. Table 5 summarizes the economic data. According to these data the silver process, without the recovery of methanol (cost of formaldehyde $ 378/t), offers the most favorable production costs, followed by the Formox process ($ 387/t) and the silver process with

Table 5. Comparison of economic factors in formaldehyde production processes [1]

		Complete methanol conversion (BASF process)	Incomplete conversion and methanol recovery	Formox process
Total capital investment, $ 10^6		6.6	8.6	9.6
Methanol consumption, t/t		1.24	1.22	1.15

Cost of production and ROI, $/t		378	407	387

recovery ($ 407/t). The two latter processes produce a product with $< 1\,\%$ methanol whereas the methanol content in the silver process without recovery lies between 1 – 5 %.

The study takes into consideration the benefit of the production of steam only in the case of the Formox process. If the production of steam is included in the silver process (3 t per tonne CH_2O without and 1.5 t per tonne CH_2O with methanol recovery) better results than demonstrated in Table 5 can be obtained (costs per tonne $ 24 and $ 12 lower, respectively). The proven capacity limits of a plant with only one reactor are about 20 000 t/a (calculated 100 %) with the metal oxide process and about 72 000 t/a with the silver process.

The key feature of the BASF process for the production of 50 wt % formaldehyde is a liquid circulation system in which heat from the absorption unit of the plant is transferred to a stripper column to vaporize the methanol – water feed. Therefore, the process produces excess steam, with simultaneous savings in cooling water.

Plant operation and start-up are simple; the plant can be restarted after a shutdown or after a short breakdown, as long as the temperatures in the stripping cycle remain high. The BASF process has several other advantages. Formaldehyde is obtained from a single pass of the methanol through the catalyst. If a lower formaldehyde concentration is needed (e.g., 40 wt %) the yield can be increased by employing a feedstock of suitably pretreated crude aqueous methanol instead of pure methanol (cf. Section 4.1.1). Deacidification by means of ion exchangers is not necessary. The off-gas does not present any problems because it is burned as a fuel gas in power stations to generate steam or steam and power. The catalyst can be exchanged within 8 – 12 h of plant shutdown to restart and can be regenerated completely with little loss. The plant is compact due to the small volume of gas that is used and the low space requirements; both factors result in low capital investment costs.

Formaldehyde production processes based on incomplete methanol conversion employ a final distillation column to recover the methanol and concentrate the formaldehyde. As shown in Table 5, this means that more steam and cooling water is consumed than in the BASF process. The BASF process has a somewhat lower yield but all other aspects are roughly comparable. Other distinctive features of the incomplete conversion of methanol are the relatively large amount of direct steam introduced into the

feedstock and the lower reaction temperature, which give a somewhat larger amount of hydrogen in the off-gas with a net calorific value of 2140 kJ/m^3. The additional ion-exchange unit also increases production costs.

The Formox process uses excess air in the methanol feed mixture and requires at least 13 mol of air per mole of methanol. A flammable mixture is used for the catalytic conversion. Even with gas recycling, the process must handle a substantial volume of gas, which is 3 – 3.5 times the gas flow in a silver-catalyzed process. Thus, the equipment must have a large capacity to accommodate the higher gas flow. The main disadvantage of the Formox process is that the off-gas is noncombustible, causing substantial costs in controlling environmental pollution. To reduce air pollution to the levels obtained in the silver-catalyzed processes, a Formox plant must burn the tail gas with sulfur-free fuel, with or without partial regeneration of energy by means of steam production. Advantages of the process are its very low reaction temperature, which permits high catalyst selectivity, and the very simple method of steam generation. All these aspects mean in easily controlled process. Plants based on this technology can be very small with annual capacities of a few thousand tons. As a result, plants employing Formox methanol oxidation are most commonly encountered throughout the world. However, if higher capacities are required and a small number of reactors must be arranged in parallel, the economic data favor the processes employing a silver catalyst.

Although approximately 70 % of existing plants use the silver process, in the 1990s new plant contracts have been dominated by the metal oxide technology [1].

4.4. Distillation of Aqueous Formaldehyde Solutions

Since formaldehyde polymerizes in aqueous solutions, the monomer content and thus the vapor pressure of formaldehyde during distillation are determined by the kinetics of the associated reactions.

Vacuum distillation produces a more concentrated bottom product and can be carried out at a low temperature, an extremely low vapor pressure, and an acid pH value of 3 – 3.4 [81]. However, the distillation rates are low, making this procedure uneconomical.

High-pressure distillation at 0.4 – 0.5 MPa and above 130 °C with long columns produces a relatively concentrated overhead product. Efficiency is high, but yields are limited due to the formation of methanol and formic acid via the Cannizzaro reaction [82].

If formaldehyde solutions are subjected to slow *distillation at atmospheric pressure* without refluxing, the distillate has a lower formaldehyde content than the bottom product [21]. If the condensate is refluxed, the ratio of condensate (reflux) to distillate determines the formaldehyde content of the distillate removed [81].

In the case of aqueous formaldehyde solutions that contain methanol, a virtually methanol-free product can be obtained by using distillation columns with a large number of plates and a relatively high reflux ratio. The product is taken from the bottom of the column [83].

4.5. Preparation of Liquid Monomeric Formaldehyde

Two methods have been described for the preparation of liquid monomeric formaldehyde from paraformaldehyde, the first was developed by F. Walker [11] and the second by R. Spence [84]. In Walker's method, liquid formaldehyde is prepared by vaporizing alkali-precipitated α-polyoxymethylene. The resultant vapor is then condensed and the crude liquid condensate is redistilled. The process is performed in an apparatus made of Pyrex glass. A vaporizing tube is charged to about one-half its height with the polymer. The thoroughly dried system is then flushed with dry nitrogen. The vaporizing tube is heated to 150 °C in an oil bath and the condensing tube is chilled in a bath of solid carbon dioxide and methanol. The polymer is vaporized in a slow stream of nitrogen by gradually raising the temperature. Formation of polymer on the tube walls is minimized by winding wire round the tubes and heating with electricity. The crude liquid product, which is opalescent due to precipitated polymer, is then distilled in a slow current of nitrogen.

According to the method of Spence, paraformaldehyde is dried over sulfuric acid in

a vacuum desiccator and introduced into a distillation flask. This flask is connected to a glass condenser via glass tubes with relatively long hairpin turns designed to separate traces of water (Fig. 4). The system is first evacuated by means of a mercury diffusion pump, and the distillation flask is then heated to 110 °C in an oil bath to remove traces of oxygen. The distillate is heated electrically to 120 °C when it flows through the upper parts of the hairpin turns; in the lower parts of the loops, it is cooled to −78 °C by means of a cooling bath. After the valve to the pump is shut and the condenser flask is cooled in liquid air, a colorless solid product condenses. The inlet and outlet tubes of the condenser flask are then sealed with a flame. The contents of the condensing flask liquefy when carefully warmed. The procedure can be repeated to obtain an even purer substance. The liquid formaldehyde that is prepared does not polymerize readily and, when vaporized, leaves only very small traces of polymeric product.

Figure 4. Apparatus for the preparation of liquid monomeric formaldehyde
a) Distillation flask; b) Glass tube with hairpin turns; c) Condenser; d) Glass wool

5. Environmental Protection

As already stated, formaldehyde is ubiquitously present in the atmosphere [85]. It is released into the atmosphere as a result of the combustion, degradation, and photochemical decomposition of organic materials. Formaldehyde is also continuously degraded to carbon dioxide in processes that are influenced by sunlight and by nitrogen oxides. Formaldehyde washed out of the air by rain is degraded by bacteria (e.g., *Escherichia coli*, *Pseudomonas fluorescens*) to form carbon dioxide and water [86].

The major source of atmospheric formaldehyde is the photochemical oxidation and incomplete combustion of hydrocarbons (i.e., methane or other gases, wood, coal, oil, tobacco, and gasoline). Accordingly, formaldehyde is a component of car and aircraft exhaust fumes and is present in considerable amounts in off-gases from heating plants and incinerators. The main emission sources of formaldehyde are summarized in Table 6.

Table 6. Sources emitting formaldehyde into the atmosphere [87]

Emission source	Formaldehyde level
Natural gas combustion	
Home appliances and industrial equipment	2400 – 58 800 μg/m^3
Power plants	15 000 μg/m^3
Industrial plants	30 000 μg/m^3
Fuel-oil combustion	0.0 – 1.2 kg/barrel oil
Coal combustion	
Bituminous	< 0.005 – 1.0 g/kg coal
Anthracite	0.5 g/kg coal
Power plant, industrial, and commercial combustion	2.5 mg/kg coal
Refuse incinerators	
Municipal	0.3 – 0.4 g/kg refuse
Small domestic	0.03 – 6.4 g/kg refuse
Backyard (garden refuse)	up to 11.6 g/kg refuse
Oil refineries	
Catalytic cracking units	4.27 kg/barrel oil
Thermofor units	2.7 kg/barrel oil
Automotive sources	
Automobiles	0.2 – 1.6 g/L fuel
Diesel engines	0.6 – 1.3 g/L fuel
Aircraft	0.3 – 0.5 g/L fuel

The formaldehyde in the exhaust gases of motor vehicles is produced due to incomplete combustion of motor fuel. Formaldehyde may be produced directly or indirectly. In the indirect route, the unconverted hydrocarbons undergo subsequent photochemical decomposition in the atmosphere to produce formaldehyde as an intermediate [88]. The concentration of formaldehyde is higher above densely populated regions than above the oceans as shown in Table 7 [89]. According to a 1976 report of the EPA [89], the proportions of formaldehyde in ambient air are derived from the main emission sources as follows:

Exhaust gases from motor vehicles and airplanes (direct production)	53 – 63 %
Photochemical reactions (derived mainly from hydrocarbons in exhaust gases)	19 – 32 %
Heating plants, incinerators, etc.	13 – 15 %
Petroleum refineries	1 – 2 %
Formaldehyde production plants	1 %

Formaldehyde in confined areas comes from the following sources:

1) Smoking of cigarettes and tobacco products [88], [90], [91]
2) Urea--, melamine--, and phenol–formaldehyde resins in particle board and plywood furniture
3) Urea – formaldehyde foam insulation
4) Open fireplaces, especially gas fires and stoves
5) Disinfectants and sterilization of large surfaces (e.g., hospital floors)

Table 7. Geographical distribution of formaldehyde in ambient air

Location	Formaldehyde concentration (max.), ppm *
Air above the oceans	0.005
Air above land	0.012
Air in German cities	
normal circumstances	0.016
high traffic density	0.056
Air in Los Angeles (before the law on catalytic combustion of exhaust gases came into effect)	0.165

* 1 ppm = 1.2 mg/m^3

Sources generating formaldehyde must be differentiated into those which release formaldehyde for a defined period, cases (1), (4), and (5) and those which release formaldehyde gas continuously, i.e., decomposition of resins as in cases (2) and (3). Many regulations have been issued to limit pollution of the atmosphere with formaldehyde in both general and special applications [92]. Protection against pollution of the environment with formaldehyde must be enforced with due attention to its sources.

The most effective limitation of atmospheric pollution with formaldehyde is the strict observation of the maximum allowable concentration indoors and outdoors. A maximum workplace concentration of 0.5 ppm (0.6 mg/m^3) has, for example, been established in the Federal Republic of Germany [93]. Other limit values and guide values have been specified for formaldehyde levels in outdoor and indoor air. Emission limits for stationary installations have also been established and regulations for specific products have been formulated. Table 8 gives a survey of regulations valid in some countries of the Western world in 1987.

In the Federal Republic of Germany formaldehyde levels and emissions are subjected to stringent regulations. Plants operating with formaldehyde must conform to the plant emission regulations introduced in 1974 which limit formaldehyde in off-gases to a maximum of 20 mg/m^3 for mass flow rates of 0.1 kg/h or more [94]. This presupposes a closed handling procedure. For example, industrial filling and transfer of formaldehyde solutions is carried out by using pressure compensation between communicating vessels. Discharge of formaldehyde into wastewater in Germany is regulated by law since it endangers water and is toxic to small animals [95]. Formaldehyde is, however, readily degraded by bacteria in nonsterile, natural water [96].

A maximum limit of 0.1 ppm formaldehyde in indoor living and recreation areas has been recommended by the BGA (German Federal Health Office) [97]. To avoid unacceptable formaldehyde concentrations in room air, the German Institute for Structural Engineering has issued guidelines for classifying particle board into emission categories E1, E2, and E3, class E3 having the highest emission [98]. The lowest class (E1) is allowed a maximum formaldehyde emission of 0.1 ppm and a maximum formaldehyde content of 10 mg per 100 g of absolutely dry board (as measured by the DIN EN-120 perforator method) [99]. Furthermore, the uses and applications of urea – formaldehyde foams, which are used to some extent for the heat insulation of cavity walls, have been controlled by DIN 18 159 [99] since 1978. No formaldehyde emission is permitted after the construction has dried.

Cigarette smoke contains 57 – 115 ppm of formaldehyde and up to 1.7 mg of formaldehyde can be generated while one cigarette is smoked. If five cigarettes are smoked in a 30 m^3 room, with a low air-change rate of 0.1 (i.e., 10 %) per hour, the formaldehyde concentration reaches 0.23 ppm [88], [91].

The best protection against accumulation of formaldehyde in confined spaces is, however, proper ventilation. The strong smell of formaldehyde is perceptible at low concentration and thus provides adequate warning of its presence. If all manufacturing and application regulations are strictly observed, possible emission of formaldehyde from consumer products

Table 8. International regulations restricting formaldehyde levels

Country	Emission limit		Product-specific regulations
	Outdoor air, ppm	Indoor air, ppm	
Canada		0.1 (1982)	Urea – formaldehyde (UF) foam insulation prohibited. Voluntary program of particle board manufacturers to reduce emission, no upper limit. Registration of infection control agents
Denmark		0.12 (1982)	Guidelines for particle board: max. 10 mg/100 g of absolutely dry board (perforator value). Guidelines for furniture and in situ UF foam. Cosmetic regulations. Prohibited for disinfecting bricks, wood, and textiles if there is contact with food
Federal Republic of Germany	0.02 (MIK_D, 1966) [a] 0.06 (MIK_K, 1966) [b]	0.1 (1977)	Particle board classification. Guidelines (GefStoffV, Gefahrstoffverordnung) for wood and furniture: upper emission limit 0.1 ppm, corresponding to 10 mg/100 mg of absolutely dry board (perforator value); detergents, cleaning agents, and conditioners: upper limit 0.2 %; textiles: compulsory labeling if formaldehyde content >0.15 %. Guidelines for in situ UF foam: upper limit 0.1 ppm. Cosmetic regulations
Finland		0.12 0.24 for pre 1983 buildings (1983)	Upper limit for particle board: 50 mg/100 g absolutely dry board (perforator value). Prohibited as an additive in hairsprays and antiperspirants. Guidelines for cosmetics, but as yet (1987) no EEC directives
Great Britain			Upper limit for particle board : 70 mg/100 g of absolutely dry board (perforator value)
Italy		0.1 (1983)	Cosmetic regulations (July 1985)
Japan			Prohibited as an additive in foods, food packaging, and paints. Guidelines for particle board, textiles, wall coverings, and adhesives
The Netherlands		0.1 obligatory for schools and rented accommodation (1978)	Particle board quality standard on a voluntary basis: upper limit 10 mg/100 g of absolutely dry boad (perforator value). Particle board regulations in preparation
Sweden		0.4 – 0.7 (1977)	Particle board and plywood quality standards: upper limit 40 mg/100 g of absolutely dry board (perforator value)
Switzerland		0.2 (introduced 1984, came into force 1986)	Particle board quality standard on a voluntary basis: upper limit 10 mg/100 g of absolutely dry board (perforator value, Oct. 1985); quality symbol "Lignum CH 10"
Spain			Regulations for in situ UF foam (1984): upper limit 1000 µg/m^3 = 0.8 ppm, 7 days after installation; 500 µg/m^3 = 0.4 ppm, 30 days after installation
United States		0.4 (Minnesota, 1984) [c] 0.4 (Wisconsin, 1982) [c]	UF foam insulation prohibited in Massachusetts, Connecticut, and New Hampshire; upper limit for existing UF-insulated houses in Massachusetts 0.1 ppm (1986). FDA limit for nailhardening preparations: 5 %. Department of housing and urban development (HUD) guidelines for emission from particleboard and plywood for the construction of mobile houses: upper limit 0.3 ppm.

[a] MIK_D = Maximum allowable concentration for constant immission (mean annual value).
[b] MIK_K = Maximum allowable concentration for short-term immission (30 min or 24 h).
[c] Replaced by HUD product standards, 1985.

is very low and will not therefore constitute a human health hazard.

Formaldehyde concentrations in cosmetic products have been limited since 1977, they must be appropriately labeled if they contain > 0.05 wt % formaldehyde [100]. Below this level, formaldehyde does not cause allergic reactions even in sensitive subjects.

6. Quality Specifications and Analysis

6.1. Quality Specifications

Formaldehyde is commercially available primarily in the form of an aqueous (generally 30 – 55 wt %) solution, and in solid form as paraformaldehyde or trioxane (cf. Chap. 11). Formaldehyde solutions contain 0.5 – 12 wt % methanol or other added stabilizers (see Chap. 7). They have a pH of 2.5 – 3.5, the acid reaction being due to the presence of formic acid, formed from formaldehyde by the Cannizzaro reaction. The solutions can be temporarily neutralized with ion exchangers. Typical product specifications for formulations on the European market are listed in Table 9. Other manufacturers' specifications are described in [102–108].

6.2. Analysis

The chemical reactivity of formaldehyde provides a wide range of potential methods for its

Table 9. Typical specifications of commercial formaldehyde solutions [101]

Formaldehyde content, wt %	Methanol content (max), wt %	Formic acid content (max), mg/kg	Iron content (max), mg/kg	Density t, °C	Density g/mL	Added Stabilizer
30	1.5	150	0.8	20	1.086 – 1.090	
37	1.8	200	1	20	1.107 – 1.112	
37	8 – 12	200	1	20	1.082 – 1.093	Methanol
37	1.8	200	1	20	1.108 – 1.112	Isophthalobisguanamine, 100 mg/kg
50	2.0	200	1	55	1.126 – 1.129	
50	2.0	200	1	40	1.135 – 1.138	Isophthalobisguanamine, 200 mg/kg

qualitative and quantitative determination in solutions and in the air.

Qualitative Methods. Qualitative detection of formaldehyde is primarily by colorimetric methods, e.g., [109], [110]. Schiff's fuchsin – bisulfite reagent is a general reagent used for detecting aldehydes. In the presence of strong acids, it reacts with formaldehyde to form a specific bluish violet dye. The detection limit is ca. 1 mL/m^3. Further qualitative detection methods are described in [111].

Quantitative Methods. Formaldehyde can be quantitatively determined by either physical or chemical methods.

Physical Methods. Quantitative determination of pure aqueous solutions of formaldehyde can be carried out rapidly by measuring their specific gravity [27]. Gas chromatography [112], [113] and high-pressure liquid chromatography (HPLC) [114–116] can also be used for direct determination.

Chemical Methods. The most important chemical methods for determining formaldehyde are summarized in [111]. The sodium sulfite method is most commonly used. This method was developed by Lemmé [117] and was subsequently improved by Seyewetz and Gibello [118], Stadtler [119], and others. It is based on the quantitative liberation of sodium hydroxide produced when formaldehyde reacts with excess sodium sulfite:

$$CH_2O + Na_2SO_3 + H_2O \rightarrow HOCH_2SO_3Na + NaOH$$

The stoichiometrically formed sodium hydroxide is determined by titration with an acid [27].

Formaldehyde in air can be determined down to concentrations in the µL/m^3 range with the aid of gas sampling apparatus [120], [121]. In this procedure, formaldehyde is absorbed from a defined volume of air by a wash liquid and is determined quantitatively by a suitable method. The quantitative determination of formaldehyde in air by the sulfite/pararosaniline method is described in [122].

A suitable way of checking the workplace concentration of formaldehyde is to take a relevant sample to determine the exposure of a particular person and to use this in combination with the pararosaniline method. The liquid test solution is transported in a leakproof wash bottle [111]. A commercial sampling tube [123], [124] can also be used, in which the formaldehyde is converted to 3-benzyloxazolidine during sampling. Evaluation is carried out by gas chromatography.

Continuous measurements are necessary to determine peak exposures, e.g., by the pararosaniline method as described in [125].

7. Storage and Transportation

With a decrease in temperature and/or an increase in concentration, aqueous formaldehyde solutions tend to precipitate paraformaldehyde. On the other hand, as the temperature increases, so does the tendency to form formic acid. Therefore, an appropriate storage temperature must be maintained (Table 10). The addition of stabilizers is also advisable (e.g., methanol, ethanol, propanol, or butanol). However, these alcohols can be used only if they do not interfere with further processing, or if they can be separated off; otherwise, effluent problems may be encountered.

The many compounds used for stabilizing formaldehyde solutions include urea [126], melamine [127], hydrazine hydrate [128], methylcellulose [129], guanamines [130], and bismelamines [33]. For example, by adding as little as 100 mg of isophthalobisguanamine [*5118-80-9*] per kilogram of solution, a 40-wt % formaldehyde solution can be stored for at least 100 d at 17 °C without precipitation of paraformaldehyde, and a 50-wt % formaldehyde solution can be stored for at least 100 d at 40 °C [32].

Table 10. Storage temperatures for commercial formaldehyde solutions

Formaldehyde content, wt %	Methanol content, wt %	Storage temperature, °C
30	≤ 1	7 – 10
37	< 1	35
37	7	21
37	10 – 12	6 – 7
50	1 – 2	45 *
50	1 – 2	60 – 65

* Stabilized with 200 mg/kg of isophthalobisguanamine

Formaldehyde can be stored and transported in containers made of stainless steel, aluminum, enamel, or polyester resin. Iron containers lined with epoxide resin or plastic may also be used, although stainless steel containers are preferred, particularly for higher formaldehyde concentrations. Unprotected vessels of iron, copper, nickel, and zinc alloys must not be used.

The flash point of formaldehyde solutions is in the range 55 – 85 °C, depending on their concentration and methanol content. According to German regulations for hazardous substances (Gefahrstoffverordnung, Appendix 6) and Appendix 1 of the EEC guidelines for hazardous substances, aqueous formaldehyde solutions used as working materials that contain ≥ 1 wt % of formaldehyde must be appropriately labeled. The hazard classifications for the transport of aqueous formaldehyde solutions with a flash point between 21 and 55 °C containing > 5 wt % formaldehyde and < 35 wt % methanol are as follows [131]:

GGVS/GGVE, ADR/RID	Class 8, number 63 c
CFR	49: 172.01 flammable liquid
IMDG Code (GGVSee)	Class 3.3
UN No.	1198

Formaldehyde solutions with a flash point > 61 °C and aqueous formaldehyde solutions with a flash point > 55 °C that contain > 5 wt % formaldehyde and < 35 wt % methanol are classified as follows:

GGVS/GGVE, ADR/RID	Class 8, number 63 c
CFR	49: 172.01 combustible liquid
IMDG Code (GGVSee)	Class 9
UN No.	2209

8. Uses

Formaldehyde is one of the most versatile chemicals and is employed by the chemical and other industries to produce a virtually unlimited number of indispensable products used in daily life [132].

Resins. The largest amounts of formaldehyde are used for producing condensates (i.e., resins) with urea, melamine, and phenol and, to a small extent, with their derivatives (see also → Amino Resins; → Phenolic Resins; → Resins, Synthetic). The main part of these resins is used for the production of adhesives and impregnating resins, which are employed for manufacturing particle boards, plywood, and furniture. These condensates are also employed for the production of curable molding materials; as raw materials for surface coating and as controlled-release nitrogen fertilizers. They are used as auxiliaries in the textile, leather, rubber, and cement industries. Further uses include binders for foundry sand, rockwool and glasswool mats in insulating materials, abrasive paper, and brake linings. A very small amount of urea – formaldehyde condensates are used in the manufacture of foamed resins (→ Foamed Plastics, Chap. 4.4., → Foamed Plastics, Chap. 4.5., → Foamed Plastics, Chap. 4.6.) that have applications in the mining sector and in the insulating of buildings.

Use as an Intermediate. About 40 % of the total formaldehyde production is used as an intermediate for synthesizing other chemical compounds, many of which are discussed under separate keywords. In this respect, formaldehyde is irreplaceable as a C_1 building block. It is, for example, used to synthesize 1,4-butanediol [*110-63-4*], trimethylolpropane [*77-99-6*], and neopentyl glycol [*126-30-7*], which are employed in the manufacture of polyurethane

and polyester plastics, synthetic resin coatings, synthetic lubricating oils, and plasticizers. Other compounds produced from formaldehyde include pentaerythritol [*115-77-5*] (employed chiefly in raw materials for surface coatings and in permissible explosives) and hexamethylenetetramine [*100-97-0*] used as a cross-linking agent for phenol – formaldehyde condensates and permissible explosives).

The complexing agents nitrilotriacetic acid [*139-13-9*] (NTA) and ethylenediaminetetraacetic acid [*60-00-4*] (EDTA) are derived from formaldehyde and are components of modern detergents. The demand for formaldehyde for the production of 4,4′-diphenylmethane diisocyanate [*101-68-8*] (MDI) is steadily increasing. This compound is a constituent of polyurethanes used in the production of soft and rigid foams and, more recently, as an adhesive and for bonding particle boards.

The so-called polyacetal plastics (→ Polyoxymethylenes) produced by polymerization of formaldehyde are increasingly being incorporated into automobiles to reduce their weight and, hence, fuel consumption. They are also used for manufacturing important functional components of audio and video electronics equipment [232].

Formaldehyde is also a building block for products used to manufacture dyes, tanning agents, dispersion and plastics precursors, extraction agents, crop protection agents, animal feeds, perfumes, vitamins, flavorings, and drugs.

Direct Use. Only a very small amount of formaldehyde is used directly without further processing. In the Federal Republic of Germany, ca. 8000 t/a are used in this way, which corresponds to ca. 1.5 % of total production. It is used directly as a corrosion inhibitor, in the metal industry as an aid in mirror finishing and electroplating, in the electrodeposition of printed circuits, and in the photographic industry for film development. However, formaldehyde as such is used mainly for preservation and disinfection, for example, in medicine for disinfecting hospital wards, preserving specimens, and as a disinfectant against athlete's foot (→ Disinfectants).

Modern hygiene requires preservatives and disinfectants to prevent the growth of microorgansims which can produce substances that may be extremely harmful to man. As an antimicrobial agent, formaldehyde displays very few side effects, but has a broad spectrum of action. All alternative agents have unpleasant or even dangerous side effects. Moreover, their toxicity has not been as thoroughly investigated as that of formaldehyde, and their spectrum of action is limited (i.e., they do not provide comprehensive disinfectant protection). Another advantage of formaldehyde is that it does not accumulate in the environment since it is completely oxidized to carbon dioxide within a relatively short time. In the cosmetics industry, formaldehyde is employed as a preservative in hundreds of products, for example, soaps, deodorants, shampoos, and nail – hardening preparations; in some of these items, upper limits have been set for the formaldehyde concentration due to its sensitizing effect (cf. Table 8). Formaldehyde solutions are also used as a preservative for tanning liquors, dispersions, crop protection agents, and wood preservatives. Furthermore, formaldehyde is required in the sugar industry to prevent bacterial growth during syrup recovery.

9. Economic Aspects

Formaldehyde is one of the most important basic chemicals and is required for the manufacture of thousands of industrial and consumer products. It is the most important industrially produced aldehyde.

Formaldehyde can seldom, if ever, be replaced by other products. Substitutes are generally more expensive; moreover, their toxicities have been less thoroughly investigated than that of formaldehyde.

Worldwide capacity [1], [231] is approximately 8.7×10^6 t/a in 1996 (see Table 11; the values are based on 100 % formaldehyde); the five largest manufactures account for ca. 25 % of this capacity:

Borden	0.66×10^6 t / a
BASF	0.444×10^6 t / a
Hoechst Celanese	0.38×10^6 t / a
Georgia Pacific	0.38×10^6 t / a
Neste Resins	0.37×10^6 t / a

The three leading countries with a capacity share of about 45 % are:

United States	1.77×10^6 t/a
Germany	1.46×10^6 t/a
Japan	0.65×10^6 t/a

Table 11. Worldwide formaldehyde production capacities in 1996 [1], [231]

Country	Total capacity, 10^3 t/a
Western Europe	3119
Germany	1464
Italy	389
Spain	265
United Kingdom	197
France	126
Sweden	124
Netherlands	115
Others	439
Eastern Europe	1850
North America	2008
United States	1772
Canada	236
South America	253
Mexico	65
Chile	63
Brazil	48
Argentina	44
Others	33
Japan	651

Formaldehyde consumption is ca. 6×10^6 t/a, although present data about capacity use in Eastern Europe are not available. The demand and the estimated average annual growth rate in the Western hemisphere is summarized in Table 12.

Table 12. Consumption of formaldehyde in the United States, Western Europe, and Japan in 1995 [1], [231]

	United States	Western Europe	Japan
Consumption, 10^6 t/a	1.37	2.22	0.52
Use, %			
Urea – formaldehyde resin	32	50	27
Melamine – formaldehyde resin	4	6	
Phenol – formaldehyde resin	24	10	6
Polyoxymethylenes	10	10	24
1,4-Butanediol	11	7	
MDI	5	6	4
Others	14	11	39
Average annual growth rate, %	2.5	1.5	2.0

Formaldehyde and its associated products are used in ca. 50 different branches of industry, as described in Chapter 8.

In the mid 1980s the sales of industrial products derived from formaldehyde was more than DM 300×10^9 in the Federal Republic of Germany [132]. At least 3×10^6 people in the Federal Republic of Germany work in factories that use products manufactured from formaldehyde.

10. Toxicology and Occupational Health

Formaldehyde toxicity was investigated extensively during the last decades and comprehensive reviews are available [233–235]. Formaldehyde is an essential intermediate in cellular metabolism in mammals and humans, serving as a precursor for the biosynthesis of amino acids, purines and thymine. Exogenously administered formaldehyde is readily metabolized by oxidation to formic acid or reacts with biomolecules at the sites of first contact. Inhalation exposure of rats, monkeys and humans to irritant concentrations did not increase blood formaldehyde levels, which were found to be around 80 mM (= 2.4 ppm) in these species.

Formaldehyde gas is toxic via inhalation and causes irritation of the eyes and the mucous membranes of the respiratory tract. Concentration – response relationship following human exposure is given in Table 13.

Table 13. Dose – response relationship following human exposure to gaseous formaldehyde [133], [134]

Effect	Exposure level, ppm
Odor threshold	0.05 – 1.0
Irritation threshold in eyes, nose, or throat	0.2 – 1.6
Stronger irritation of upper respiratory tract, coughing, lacrimation, extreme discomfort	3 – 6
Immediate dyspnea, burning in nose and throat, heavy coughing and lacrimation	10 – 20
Necrosis of mucous membranes, laryngospasm, pulmonary edema	> 50

Aqueous formaldehyde solutions cause concentration dependent corrosion or irritation and skin sensitization. There is no evidence for Formaldehyde to cause respiratory allergy [236].

In *chronic inhalation* studies with rats, mice, hamsters, and monkeys no systemic toxicity occurred in irritant concentrations. Upper respiratory tract irritation ceased at concentrations < ca. 1 ppm. At concentrations above 1 – 2 ppm changes in the nasal mucosa (respiratory epithelium) occur. At high concentrations (15 – 20 ppm) olfactory epithelium, laryngeal mucosa, and proximal parts of the tracheal epithelium might also be affected. The lesions are characterized by epithelial hyperplasia and metaplasia. Studies using other routes of administration also failed to show systemic toxicity or reproductive effects.

Formaldehyde was *genotoxic* in several in vitro test systems. In animals, there are some indications of in vivo genotoxicity in tissues of initial contact (portal of entry) but not in remote organs or tissues. In workers exposed to formaldehyde no systemic genotoxicity and no convincing evidence of local genotoxicity was found.

No evidence of systemic *carcinogenicity* was found after oral dermal and inhalative administration of formaldehyde. Several chronic inhalation studies in rats showed development of nasal tumors starting at concentrations at or above 6 ppm, causing in addition severe chronic epithelial damage in the nasal epithelium [237]. The nonlinear concentration response curve shows a disproportionately high increase in tumor incidence at concentrations of 10 and 15 ppm. The same nonlinear concentration response was observed for DNA protein cross-link (DPX) formation in nasal mucosa, which is a surrogate of formaldehyde tissue "dose", and for increase in cell proliferation in nasal epithelium. This leads to the suggestion that increased cell proliferation is a prerequisite for tumor development [237]. Chronic inhalation studies in mice failed to show statistically significant increases in tumor incidences at similar concentrations while in hamsters no nasal tumors were found. This may be attributed to differences in local formaldehyde tissue dose or lower susceptibility of the species for nasal tumor formation.

In humans numerous *epidemiological studies* failed to give convincing evidence of carcinogenicity [235]. IARC [234] concluded that the epidemiologic data available represent "limited evidence of carcinogenicity" and classified formaldehyde as "probably carcinogenic to humans (Group 2A)". The European Union categorizes the compound as "possibly carcinogenic to humans (Class 3)".

Current occupational exposure limits in different countries vary between 0.3 and 2 ppm [238]. Proposed limit values for indoor air are in the range of 0.1 ppm [239].

11. Low Molecular Mass Polymers

The ability of formaldehyde to react with itself to form polymers depends directly on the reactivity of formaldehyde as a whole. Two different types of formaldehyde polymers are possible and are based on the following structural elements:

1) $-CH_2-O-$
2) $-CH(OH)-$

The polyhydroxyaldehydes consist of the structural unit (2). The highest molecular mass representatives of this group are the sugars. Although these substances can be made by aldol condensation of formaldehyde, they do not revert to formaldehyde on cleavage, and are not discussed in this article.

The representatives of group (1), the real formaldehyde polymers (polyoxymethylenes), revert to formaldehyde on cleavage and, therefore, can be considered as a solid, moisture-free form of formaldehyde. If these linear or cyclic compounds contain no more than eight formaldehyde units, they are defined as low molecular mass polymers. The high molecular mass substances are the real polymers (paraformaldehyde, acetal plastics, see also → Polyoxymethylenes). Chemical and physical analyses of these low and high molecular mass compounds as well as investigation of their chemical reactions led to the elucidation of the molecular structure of polymers in general [135].

11.1. Linear Polyoxymethylenes

Apart from the poly(oxymethylene) glycols, also called poly(oxymethylene) dihydrates or simply polyoxymethylenes, of the formula $HO-(CH_2O)_n-H$, derivatives such as poly(oxymethylene) diacetates $CH_3COO(CH_2O)_nCOCH_3$ and

poly(oxymethylene) dimethyl ethers $CH_3O(CH_2O)_nCH_3$ should be mentioned. Some of their physical properties are given in Table 14. The *n* values of the real low molecular mass polyoxymethylenes are 2 – 8; the *n* values of paraformaldehyde are 8 – 100. However, high polymers with a degree of polymerization $n \geq 3000$ are also obtained. The polyoxymethylenes are also classified as α, β, γ, δ, and ε polymers which are of historical importance. They differ in their degrees of polymerization and in their chemical structures (Table 15). Their toxicology is the same as that of formaldehyde (see Chap. 10).

The lower poly(oxymethylene) glycols are colorless solids with melting points between 80 and 120 °C (Table 14). In contrast to the high molecular mass materials, they dissolve in acetone and diethyl ether without or with only slight decomposition; they are insoluble in petroleum ether. When dissolved in warm water, they undergo hydrolysis to give a formaldehyde solution. The low molecular mass polymers constitute a homologous series, whose properties change continuously with the degree of polymerization.

A freshly prepared, aqueous formaldehyde solution polymerizes to the lower polymers when allowed to stand (see also Section 2.2). Indeed, formaldehyde exists in dilute solution as dihydroxymethylene (formaldehyde hydrate), which in turn undergoes polycondensation to yield low molecular mass poly(oxymethylene) glycols:

$$CH_2O + H_2O \Leftrightarrow HO{-}CH_2{-}OH + n\,HOCH_2OH \Leftrightarrow HO{-}CH_2O{-}(CH_2O)_n{-}H + n\,H_2O$$

Equilibrium is attained under the influence of a hydrogen ion catalyst. At a low temperature and a high concentration, equilibrium favors formation of high molecular mass polymers. However, the major product is of lower molecular mass when the system is heated. The polymers partially separate out, crystallize, and slowly undergo further condensation polymerization [140]. The low molecular mass substances can be further precipitated and isolated by concentrating the solution at low temperature under vacuum conditions; the polymers can be further precipitated by evaporation [141]. The resulting mixture can be separated into the individual substances by exploiting their varying solubilities in different solvents [135].

The transformation of poly(oxymethylene) dihydrates to diacetates and, above all, to diethers produces a remarkable increase in thermal and chemical stability. This is because the unstable hemiacetals at the ends of the chains are eliminated through saturation of the hydroxyl groups. The diethers are stable up to 270 °C in the absence of oxygen and up to 160 °C in the presence of oxygen. These diethers and diacetates are resistant to hydrolysis under neutral conditions, the diethers are also stable in the presence of alkali. Similar to the dihydrates, the properties of the diacetates and diethers also change continuously as the degree of polymerization increases (see Table 14).

Poly(oxymethylene) diacetates are produced by the reaction of paraformaldehyde with acetic anhydride [135]. Pure products are isolated by vacuum distillation, solvent extraction, and crystallization.

The formation of poly(oxymethylene) dimethyl ethers involves the reaction of poly(oxymethylene) glycols or paraformaldehyde with methanol at 150 – 180 °C in the presence of traces of sulfuric or hydrochloric acid in a closed vessel [135]. Alternatively, they can be synthesized by the reaction of formaldehyde dimethyl acetal with either paraformaldehyde or a concentrated formaldehyde solution in the presence of sulfuric acid. This synthesis can be varied by substituting other formaldehyde dialkyl acetals for the dimethyl compound [142].

Paraformaldehyde [*30525-89-4*] was first produced in 1859. This polymer, at first mistakenly called dioxymethylene and trioxymethylene, consists of a mixture of poly(oxymethylene) glycols $HO{-}(CH_2O)_n{-}H$ with $n = 8 - 100$. The formaldehyde content varies between 90 and 99 % depending on the degree of polymerization *n* (the remainder is bound or free water). It is an industrially important linear polyoxymethylene.

Properties. Paraformaldehyde is a colorless, crystalline solid with the odor of monomeric formaldehyde. It has the following physical properties: *fp* 120 – 170 °C, depending on the degree of polymerization; heat of combustion 16.750 kJ/kg (product containing 98 wt % formaldehyde); energy of formation

∗ Values up to 58 °C according to [143] and from 65 – 120 °C according to [144].

Even at ambient temperature, paraformaldehyde slowly decomposes to gaseous formaldehyde (Table 16), a process which is greatly accelerated by heating. Depolymerization is based on a chain "unzipping" reaction which starts at the hemiacetal end groups of the individual molecules. The rate of decomposition therefore depends on the number of end groups, i.e., on the degree of polymerization.

Paraformaldehyde contains only a few acetone-soluble components (lower diglycols). It dissolves slowly in cold water, but readily in warm water where it undergoes hydrolysis and depolymerization to give a formaldehyde solution. Although this solution is generally cloudy as a result of impurities, these can be removed by filtration. Indeed, the resulting solution is identical with the solution obtained on dissolving gaseous formaldehyde in water. Not only heat, but also dilute alkali or acid increase the solubility of paraformaldehyde. Alkali catalyzes formaldehyde cleavage at the chain ends, acid causes additional splitting at the oxygen bridges. The rate constant of dissolution passes through a minimum between pH 2 and 5, it increases rapidly above and below this pH range [145]. The situation becomes more complex at higher concentrations of formaldehyde in the solution

due to the incipient back reaction. Solubility in nonaqueous solvents is also improved in the presence of acidic or alkaline agents as a result of the onset of depolymerization. Paraformaldehyde also dissolves in alcohols, phenols, and other polar solvents, in which depolymerization and solvation can occur.

Production. Paraformaldehyde is prepared industrially in continuously operated plants by concentrating aqueous formaldehyde solutions under vacuum conditions. At first, colloidal, waxy gels are obtained, which later become brittle. The use of a fractionating column through which gases were passed dates from about 1925 [146], [147].

Paraformaldehyde is currently produced in several steps which are carried out at low pressure and various temperatures [148], [149]. Highly reactive formaldehyde is produced under vacuum conditions starting with solutions that contain 50 – 100 ppm of formic acid and also 1 – 15 ppm of metal formates where the metals have an atomic number of 23 – 30 (e.g., Mn, Co, and Cu) [150]. The solutions are processed in thin-layer evaporators [151] and spray dryers [152].

Other techniques such as fractional condensation of the reaction gases in combination with the formaldehyde synthesis process [153] and very rapid cooling of the gases [154] are also applied. Alternatively, formaldehyde-containing gas is brought into contact with paraformaldehyde at a temperature that is above the dew point of the gas and below the decomposition temperature of paraformaldehyde [155]. The product is obtained in the form of flakes when a highly concentrated formaldehyde solution is poured onto a heated metal surface. The hardened product is subsequently scraped off and thoroughly dried [156]. Paraformaldehyde beads are produced by introducing a highly concentrated melt into a cooling liquid (e.g., benzene, toluene, cyclohexane [157]. Acids [158] and alkalis [148], [159] are also added; they apparently accelerate polymerization and lead to the formation of higher molecular mass but less reactive paraformaldehyde.

Highly soluble, highly reactive paraformaldehyde with a low degree of polymerization is very much in demand. It is produced from concentrated, aqueous – alcoholic formaldehyde solutions [160], [161].

Stabilizing agents include hydantoins [162], nicotinamide, and succinamide [163].

Producers. The main producers of paraformaldehyde are Degussa (Federal Republic of Germany), Ticona (owned by Hoechst, United States), Mitsui Toatsu, and Mitsubishi Gas (Japan). Smaller producers include Derivados Forestales (Spain), Synthite (United Kingdom), Alder (Italy), and Lee Chang Yung (Taiwan).

Quality Specifications. An important factor regarding the quality of paraformaldehyde is its tendency to "age", especially under the influence of heat, which results in decreased reactivity. The paraformaldehyde loses its residual water and becomes brittle. This may be prevented by storage below 10 °C; in a moist atmosphere regeneration is possible. After production, the residual moisture in the product should therefore be retained.

Reactivity is determined with the aid of the resorcinol test in which the rate at which paraformaldehyde condenses with resorcinol in an alkaline medium is measured [162]. The formaldehyde content is measured by using the sodium sulfite method (cf. Section 6.2) and the water content by the Karl Fischer method.

Transport and Storage. Paraformaldehyde is stored and transported as granules or a free-flowing coarse powder in bags, containers, and in silos or silo wagons. Cool, dry conditions must be maintained.

Uses. Paraformaldehyde is used in place of aqueous formaldehyde solutions, especially in applications where the presence of water interferes, e.g., in the plastics industry for the preparation of phenol, urea, and melamine resins, varnish resins, thermosets, and foundry resins. Other uses include the synthesis of organic products in the chemical and pharmaceutical industries (e.g., Prins reaction, chloromethylation, Mannich reaction), the production of textile auxiliaries (e.g., for crease-resistant finishes), and the preparation of disinfectants and deodorants.

11.2. Cyclic Polyoxymethylenes

11.2.1. Trioxane

1,3,5-Trioxane [*110-88-3*], trioxymethylene, or 1,3,5-trioxycyclohexane, $C_3H_6O_3$, M_r 90.1, is

the cyclic trimer of formaldehyde and was first produced and identified in 1885. A laboratory oddity for many years, this substance is very important today, especially as an intermediate in the production of acetal resins (polyoxymethylenes).

Physical Properties. Trioxane is a white crystalline solid with a characteristic odor resembling that of chloroform. Other physical properties are as follows (see also [164]):

fp	62–63 °C
bp	115 °C
Density of crystals	1.39 kg/m^3
Density of liquid at 65 °C	1.17 kg/m^3

For the spectroscopic analytical identification of trioxane, see [164]. The compound forms an azeotropic mixture with 30 wt % water, *bp* 91.3 °C.

Trioxane is soluble in water (0.172 g/cm^3 at 18 °C, 0.211 g/cm^3 at 25 °C and completely soluble at 100 °C), alcohol, ketones, organic acids, ethers, esters, phenols, aromatic hydrocarbons, and in chlorinated hydrocarbons; however, it is only sparingly soluble in aliphatic hydrocarbons.

Like dioxane and other cyclic ethers, melted trioxane, (mixed with water if necessary) is an excellent solvent for organic substances. It forms addition compounds with phenol and 1,3,5-trinitrobenzene.

Studies of vapor-liquid equilibria of systems containing formaldehyde, water, methanol, and trioxane are available [220], [224], [226].

Chemical Properties. Trioxane is stable up to 224 °C. Like acetals, it is hydrolyzed by aqueous solutions of strong acids. However, trioxane is inert under neutral and alkaline conditions. For this reason, the usual detection methods for formaldehyde, such as the sodium sulfite method, cannot be applied directly. Formaldehyde in acetals, and thus trioxane, can be determined by heating in water in the presence of a strong acid (e.g., sulfuric acid) to convert the product to monomeric formaldehyde. The formaldehyde can then be determined by the sulfite method (see Section 6.2).

The acid-catalyzed hydrolysis of trioxane is accelerated by using stronger acids, higher acid concentrations, and nonaqueous solvents. When trioxane is heated in nonaqueous systems in the presence of either strong acids (sulfuric acid, hydrochloric acid, zinc chloride, iron chloride etc.) or comonomers, it is converted to high molecular mass oxymethylene homopolymers or oxymethylene copolymers, respectively. This method is applied today in the large-scale production of acetal resins. If additional substances which react with formaldehyde (e.g., phenols, melamine) are also present during these hydrolytic or moisture-free reactions, then the nascent formaldehyde reacts very vigorously with them.

Production. Trioxane is prepared by the trimerization of formaldehyde. At first, the starting materials used were paraformaldehyde or polyoxymethylenes which were heated with acid, usually sulfuric acid [165]. As the commercial importance of trioxane grew, aqueous formaldehyde solutions and high formaldehyde concentrations [166] were introduced. World production in 1987 was 250 000 t, in 1997 about 380 000 t.

The currently preferred process for trioxane production is illustrated in Figure 5 (see also [167]). Commercial aqueous formaldehyde is

concentrated to 60 – 65 wt % in a column (a) under vacuum conditions. The 60 – 65 % formaldehyde solution is fed into the reactor (b). A dilute (6 – 10 %) formaldehyde solution is removed and, if necessary, can be reconcentrated by pressure distillation and returned to the process. In the reactor (b), formaldehyde is trimerized in the presence of a catalyst (e.g., sulfuric acid, phosphoric acid, ion exchanger [168], or heteropoly acid [169]) which is present at a concentration of up to 25 wt % [170]. Technical and kinetic experiments designed to achieve optimal reactor conditions are described in [171]. A mixture of trioxane, formaldehyde, and water is distilled off and, if necessary, concentrated in a distillation column [172]. In the extraction column (c) [173], the trioxane is extracted from the aqueous mixture by using methylene dichloride [*75-09-2*] [166] or another inert, water-immiscible solvent (benzene [174], 1,2-dichloroethane [175], or nitrobenzene [176]). The formaldehyde – water mixture is returned to the concentrating column (a). The trioxane – methylene dichloride mixture is separated in the distillation column (d). The crude trioxane is obtained at the bottom of the column and the methylene dichloride as overhead product. The trioxane is subsequently purified by distillation in column (e). The solvent methylene dichloride is freed of impurities in the solvent purification step (f) and recycled to the extraction column (c).

Impurities and byproducts (formic acid, methyl formate, dimethylformal, and formaldehyde) can be eliminated by washing with sodium hydroxide solution after the extraction step [177]. Emulsification of the reaction mixture in an inert, nonvolatile liquid, e.g., paraffin oil, may reduce the formation of paraformaldehyde in the reactor [178]. Addition of inert organic substances with low dielectric constants to the trimerization mixture increases conversion [179]. Special processes in a synthesis reactor have also been described [180]. Crystallization of liquid trioxane and contact with an inert gas stream can be used for further purification, especially from higher homologues of bis (methoxymethyl) ether [181].

In the last years a new method has been proposed to remove trioxane from the mixture of trioxane, formaldehyde, and water. After trimerization formaldehyde is separated by pervaporation, e.g., with a polyether block amide membrane [182], [183].

Since water is added with the aqueous formaldehyde solution, the energy requirement for trioxane production is very high (14 – 17 t of steam per ton of trioxane). This may be reduced by using a process based on the trimerization of gaseous formaldehyde with Lewis acids [184] and catalyzed by vanado- and/or molybdo and/or wolframo-phosphoric acids [185–187].

Trioxane can be produced by recycling of poyoxymethylenes (POM) [188], [189].

Producers. Ticona (owned by Hoechst, Federal Republic of Germany and United States), Ultraform (owned by BASF and Degussa, Federal Republic of Germany and United States), Polyplastics (owned by Hoechst and Daicel, Japan), Mitsubishi Gas Chemical (Japan), Asahi (Japan), Korean Engineering Plastics (owned by Tong Yang Nylon and Mitsubishi Gas Chemical, Korea), Taiwan Engineering Plastics, Tepco (owned by Polyplastics and Chang Chun Group, Taiwan), Formosa Plastics (Taiwan), Tarnoform (Poland). The world capacity is about 400 000 t.

Uses. The production of plastics (polyoxymethylene plastics, POM) is the most important commercial application of trioxane and requires extremely pure material. Since trioxane depolymerizes to produce formaldehyde, it can be used in almost all formaldehyde reactions, especially when anhydrous formaldehyde is desired. Trioxane is used, e.g., as a textile auxiliary; in various cross-linking agents, for instance for pitch fibers in manufacturing of carbon fibers; for stabilization and reinforcement of wood to produce musical instruments; and in distillable binders in ceramic compositions for shaped articles, e.g., in an injection moulding process. It is also employed in the stabilization and deodorization of waxes, as an anticorrosive additive for metals (especially when corrosion is caused by chlorinated hydrocarbons) [190], as an additive in photographic developers, as a solid fuel, in coating removers and, because of its hydrolysis to formaldehyde in presence of acid, in disinfectants.

Storage and Transport. Liquid trioxane is stored and transported in heated tanks. Solid tri-

Figure 5. Trioxane production
a) Concentration column; b) Reactor; c) Extraction column; d, e) Distillation columns; f) Solvent purification

oxane is transported in drums, trioxane flakes are transported in drums and bags.

Toxicology. Trioxane is not known to display any special toxic reactions; its oral LD_{50} value in rats is > 3200 mg/kg. Hydrolysis in the presence of acid produces formaldehyde (see Chap. 10).

11.2.2. Tetraoxane

1,3,5,7-Tetraoxane [*293-30-1*], tetraoxymethylene, or 1,3,5,7-tetroxocane, $C_4H_8O_4$, M_r 120, is the cyclic tetramer of formaldehyde and is a crystalline solid (*fp* 112 °C). Tetraoxane vapors are stable even at 200 °C (*bp* at 101.3 kPa, 163 – 165 °C).

Tetraoxane is produced by heating a water-insoluble, high molecular mass poly(oxymethylene) diacetate [165]. In the tetramerization of formaldehyde, metal sulfates may be used as catalyst [191].

Tetraoxane accumulates as a high-boiling substance in the distillation residue obtained during the production of trioxane. It is also obtained in the polymerization of trioxane and can be isolated by extraction with, for example, ethylbenzene [192]. The formation of tetraxane by irradiation of carbon monoxide and hydrogen has also been described [193].

Tetraoxane is a more favorable textile auxiliary for achieving crease resistance, e.g., for cellulose fibers, than trioxane because of its higher boiling point. Like trioxane, tetraoxane can also be employed in the production of acetal plastics.

11.2.3. Higher Cyclic Polyoxymethylenes

Higher cyclic polyoxymethylenes can also undergo polymerization. The tendency to polymerize in the melt decreases with increasing ring size.

1,3,5,7,9-Pentoxecane [*16528-92-0*], pentaoxane, pentaoxacyclodecane, or pentaoxymethylene, $C_5H_{10}O_5$, the cyclic pentamer of formaldehyde, is a crystalline product (*fp* 55 – 56 °C). The polymerization of trioxane with the aid of a tin tetrachloride catalyst produces several cyclic homologues including pentoxecane [194].

The fractional distillation and subsequent preparative gas chromatography of residues from the commercial trioxane polymerization affords 1,3,5,7,9-pentoxecane [195].

Although *hexoxecane* (six formaldehyde units) has not clearly been identified in the residue, *Pentadecoxane* (15 formaldehyde units) has been unambiguously detected (*fp* 68 – 70 °C). Pentoxecane is used in addition

to tetraoxane in patent formulations for the shrinkproofing of cotton [196].

12. Formaldehyde Cyanohydrin

Formaldehyde cyanohydrin [*107-16-4*], $CH_2(OH)CN$, M_r 57.05, is also known as hydroxyacetonitrile, glycolonitrile, or glycolic nitrile. It is less commercially important than acetone cyanohydrin (→ Acetone, Chap. 11.1.) but of about the same importance as the cyanohydrin derivatives of acetaldehyde, benzaldehyde, and ethylene.

Physical Properties. Formaldehyde cyanohydrin is a colorless liquid with an odor similar to that of hydrogen cyanide. It is soluble in water, ethanol, and diethyl ether but insoluble in chloroform and benzene. For IR spectrum see [197]. Other physical properties follow:

mp	−72 °C
bp at	
101.3 kPa	183 °C (slight decomp.)
3.2 kPa	119 °C
0.4 kPa	76.5 – 78 °C
Relative density d_4^{19}	1.1039
n_D^{20}	1.4112
Electrolytic dissociation constant k at 25 °C	0.843×10^{-5}
Dielectric constant	178

Chemical Properties. Like all cyanohydrins, reactions can occur at both the nitrile and the hydroxyl groups of formaldehyde cyanohydrin. Heating at 100 °C with water yields hydroxyacetamide, acid-catalyzed hydrolysis yields hydroxyacetic acid. Reaction with absolute ethanol in the presence of hydrochloric acid produces ethyl hydroxyacetate [198]. *N*-Substituted amides can be synthesized by heating formaldehyde cyanohydrin with amines in water [199]. Catalytic hydration (Ni – Al catalysts) of the nitrile group gives amines. The resulting mixtures can be separated into primary, secondary, and tertiary β-hydroxyethyleneamines [200].

The hydroxyl group of formaldehyde cyanohydrin can be replaced by other electronegative groups. For example, reaction with ammonia gives amino nitriles including nitrilotriacetonitrile $N(CH_2CN)_3$ which is an intermediate in the synthesis of nitrilotriacetic acid (NTA) [201]. Ethylenediaminetetraacetonitrile is similarly synthesized from formaldehyde cyanohydrin and ethylene diamine in the presence of sulfuric acid as a catalyst. Subsequent hydrolysis yields ethylenediaminetetraacetic acid (EDTA) [201]. The reaction of cyanohydrins with ammonia is a step in the Strecker synthesis of amino acids. Hydration of formaldehyde cyanohydrin and subsequent treatment with an aqueous solution of sodium cyanide and ammonia (Bucherer reaction, a variant of the Strecker synthesis) leads to *DL*-serine [202].

Formaldehyde cyanohydrin reacts with hydrogen halides or phosphorus pentachloride to form α-halonitriles. In aqueous solutions at pH 8 and a temperature of 10 °C or less, it trimerizes to form 4-amino-2,5-bis(hydroxymethyl)-pyrimidin-5-ol [203]. Hydantoin can be synthesized by reacting formaldehyde cyanohydrin with carbon dioxide, ammonia, or ammonium carbonate at high pressure [204], [205].

Production. Formaldehyde cyanohydrin is formed in 79.5 % yield when 37 % formaldehyde is mixed with a stoichiometric amount of aqueous hydrogen cyanide for 1 h at 2 °C in the presence of sodium hydroxide as a catalyst [206]. Patents also describe synthesis by (1) heating formaldehyde with hydrogen cyanide at 250 °C [207] or in the presence of sulfur dioxide at pH 1.5 – 2.0 in an aqueous medium [208] and (2) by reacting acetonitrile with oxygen and with or without water at high pressure in the presence of various vanadium oxides [209–211].

Formaldehyde cyanohydrin is generally handled as an aqueous solution but it can also be isolated in the anhydrous state by ether extraction, drying, and vacuum distillation [212]. Although the extremely pure product is reported to be very stable [213], addition of a small amount of stabilizer (e.g., monochloroacetic, mercaptoacetic, lactic, sulfonilic, and phosphoric acids) is advisable [214]. Monochloroacetic acid is especially suitable because it codistils with the product. Cyanohydrin with a lower degree of purity is not very stable, especially at high pH values, this should be borne in mind when handling anhydrous formaldehyde cyanohydrin (see also [203]).

Transport and Storage. Formaldehyde cyanohydrin is used almost exclusively as an

intermediate and is normally produced at the site where it is to be processed. However, it is also supplied as a 70 % aqueous solution and is transported in steel containers and tank cars. Attention should be paid to stabilization during transport and storage. Impure formaldehyde cyanohydrin can decompose to give formaldehyde and hydrogen cyanide, attention should therefore be paid to explosion and fire hazards.

Toxicology. Formaldehyde cyanohydrin, like all cyanohydrins, is extremely toxic when inhaled or ingested and moderately toxic when absorbed via the skin [215]. All forms of contact should be avoided because of the possible formation of hydrogen cyanide or cyanides.

1. Introduction

Formamides are derivatives of the smallest of the aliphatic carboxylic acids, formic acid, and are thus structurally and chemically rather straightforward substances. Two of the simplest members of the family–formamide itself [*75-12-7*], $HCONH_2$, and *N,N*-dimethylformamide [*68-12-2*], $HCON(CH_3)_2$–have considerable industrial importance because of their chemical bifunctionality and high polarity. Formamide is especially valued for its chemical reactivity; *N,N*-dimethylformamide is used widely for its solvent properties.

Formamide (methanamide) was first prepared by A. W. HOFFMANN in 1863 by reaction of ethyl formate with ammonia. The compound became commercially important only after the development of high-pressure syntheses based on carbon monoxide and ammonia, to yield formamide directly or via the intermediate methyl formate. *N,N*-Dimethylformamide (formyldimethylamine) was reported in 1893 by VERLEY, who obtained it upon distillation of a mixture of calcium formate and dimethylamine hydrochloride. Referred to commonly as "DMF," this compound is a key solvent in numerous operations, especially the spinning of synthetic fibers (a development of the 1950s).

No other member of the formamide family has achieved the industrial importance of these two substances.

2. Formamide

2.1. Physical Properties

Formamide [*75-12-7*], CH_3NO, M_r 45.04, is a hygroscopic, clear, colorless, odorless, and pH-neutral liquid with a consistency like that of glycerol. It melts at 2.55 °C and boils (decomp.) at 210 °C (101.3 kPa). Below 80 °C, the substance exhibits a greater degree of association than water, although this association diminishes rapidly with increasing temperature. The most important physical properties of formamide may be summarized as follows:

mp	2.55 °C
bp (at 101.3 kPa)	210 °C (decomp.)
Density ϱ (at 20 °C)	1.1334 g/cm^3
(at 50 °C)	1.1078 g/cm^3
Refractive index n_D^{15}	1.4491
n_D^{20}	1.4468
Dynamic viscosity η (at 15 °C)	4.320 mPas
(at 30 °C)	2.926 mPas
Surface tension σ (at 20 °C)	0.0582 N/m
Coefficient of expansion α	0.000742 cm^3/K
Specific heat $c^{19}{}_p$	2300 J kg^{-1}K^{-1}
Thermal conductivity λ (at 40 °C)	0.352 W m^{-1}K^{-1}
Heat of vaporization	1673 kJ/kg
Heat of combustion	12 530 kJ/kg
Heat of formation (at 18 °C)	−3529 kJ/kg
Electrical conductivity (at 25 °C)	$2\times10^{-7}\,\Omega^{-1}\,cm^{-1}$
Dielectric constant (at 25 °C) (wavelength 1 – 5 m)	109 ± 1.5
Dipole moment (at 30 °C)	3.37 D
Flash point (Abel Martens)	175 °C
Ignition temperature (DIN 51 794)	>500 °C
Explosive limits in air	2.7 – 19 vol %

Vapor pressure of formamide at various temperatures

t, °C	70.5	122.5	157.5	193.5	210
p, kPa	0.13	2.67	13.33	53.32	101.3 (decomp.)

Because of its high polarity and dielectric constant, formamide is an effective nonaqueous solvent for many inorganic salts, including chlorides, iodides, nitrates, phosphates, and carbonates. Formamide itself is very soluble in polar solvents such as water, lower aliphatic alcohols, carboxylic acids, esters, glycols, acetone, phenol, chloroform, and ether. Many high molecular mass polymers, natural products, and dyes also exhibit solubility or swelling in formamide. Examples include peptones and proteins (e.g., keratin), saccharides (e.g., cellulose and starch), and poly(vinyl alcohol). By contrast, hydrocarbons, fats, and oils have little solubility in formamide.

2.2. Chemical Properties

Pure formamide is a slightly hygroscopic liquid that is stable to the effects of light and atmospheric oxygen below ca. 100 °C. Above this limit, and especially above 160 °C, significant decomposition occurs. The decomposition rate reaches 0.5 % per minute at the atmospheric pressure boiling point. Principal decomposition products are carbon monoxide and ammonia, along with smaller amounts of hydrogen cyanide and water. Further transformation products are also detectable, including polymeric hydrogen cyanide derivatives. Above 500 °C, and with the aid of catalysts such as aluminum oxides or aluminum silicates, decomposition can be so accelerated that hydrogen cyanide yields may exceed 90 %. Formamide is stabilized by the presence of traces (e.g., 0.001 wt %) of purine bases [7].

Formamide is quite stable to water at room temperature. However, at elevated temperatures it undergoes hydrolysis to formic acid and ammonia, a combination that appears as ammonium formate. Both acid and alkali accelerate this hydrolysis, and the reaction of sulfuric acid with formamide at high temperature produces a nearly quantitative yield of formic acid. Until recently, this process served BASF as the basis for industrial-scale preparation of formic acid; today, however, direct synthesis of formic acid by high-pressure hydrolysis of the formamide precursor methyl formate is more economical, because the formation of ammonium sulfate as a side product is avoided (→ Formic Acid, Chap. 4.). Alkaline hydrolysis of formamide leads to alkali formates and ammonia, a reaction that can be used for quantitative analysis of formamide.

Formamide has attracted commercial interest not only because of its favorable solvent characteristics but also because of its bifunctional nature, which makes it a valuable component in many synthetic sequences. It is particularly useful as a formylating reagent, e.g., in the N-formylation of primary and secondary amines. Formamide can also serve as the starting point for substituted formamides (e.g., formanilide [*103-70-8*]), which are obtained by transamidation. It is used in the preparation of nitrogen-containing heterocycles such as theophylline [*58-55-9*], caffeine [*58-08-2*], pyrimidine [*289-95-2*], and imidazole [*288-32-4*]. Formate esters are produced by the reaction of formamide with the corresponding alcohols in the presence of an acid catalyst. Formamide reacts with acyl chlorides to give triacylamines [8]. Reaction with sodium methoxide produces sodium diformylamide [*18197-26-7*] [9].

2.3. Production

The production of formamide when carbon monoxide and ammonia are heated under pressure and subjected either to dark electrical discharge or to the catalytic effects of ceramic fragments has been known since the beginning of this century. However, the work of R. Wietzel in 1924 led to the first economical, continuous process for the manufacture of formamide. His results showed that alkyl formates, especially methyl formate, could be produced in satisfactory yield at high pressure (25 MPa) and low temperature (30 – 140 °C) with the aid of alkali alkoxide catalysts, thus establishing what is now referred to as the two-step formamide synthesis [10]. Wietzel also introduced a direct synthesis of formamide from carbon monoxide and ammonia in the presence of alcohols as a solvent, again promoted by alkali alkoxides [11].

Modern facilities for the preparation of formamide utilize either this *direct synthesis*,

$$CO + NH_3 \xrightarrow{NaOCH_3} HCONH_2$$

or the indirect *two-step process*:

$$CO + CH_3OH \xrightarrow{NaOCH_3} HCOOCH_3$$

$$HCOOCH_3 + NH_3 \longrightarrow HCONH_2 + CH_3OH$$

Direct Synthesis. In the direct synthesis of formamide, carbon monoxide or a gas mixture containing carbon monoxide is mixed with ammonia (either in stoichiometric amounts or in excess) and subjected to the catalytic action of alkoxides dissolved in alcohol (usually methanol). Other potential catalysts have been examined, including organometallic compounds from groups 4 – 10 of the periodic table (i.e., titanium to nickel), but these have not proved satisfactory so far [12]. The amount of catalyst required depends on the extent to which catalyst poisons are present, i.e., substances such as water that lead to undesirable side reactions. Poisons of this type render a portion of the catalyst inactive, causing it to precipitate from the reaction mixture in the form of sodium formate. Requisite pressures are 0.8 – 1.7 MPa at 75 – 80 °C [13]. Ammonia may be introduced in either liquid or gaseous form. Pure carbon monoxide is suitable for the process, but so is a gas mixture containing carbon monoxide, such as the coke-oven gas or blast-furnace gas obtained from a steel mill [14]. Water, hydrogen sulfide, and carbon monoxide are potential catalyst poisons and must be removed from the starting material, but hydrogen and inert gases pose no problem.

The direct synthesis of formamide actually consists of a series of steps, including synthesis, methanol recovery, catalyst recovery, salt removal, and final product purification. A separate purification step (flushing with water or separation of formamide by distillation) is necessary because impurities collect during salt removal [15], [16]. Because starting materials and product are both corrosive and stringent purity standards exist with respect to iron contamination, exposure to iron must be avoided. According to that, stainless steel is used as material of construction.

Two-Step Process. The two-step approach to formamide synthesis (as practiced, for example, by BASF) begins with ordinary commercial (96 %) methyl formate and ammonia. No other starting materials are involved, so this process avoids the problem posed in direct synthesis by residual salts and other impurities. Thus, no overhead distillation of formamide is required. Apart from excess starting materials, the only byproducts are traces of entrained water and inert gas, both of which can be removed easily by distillation to yield formamide of >99.5 % purity. The process divides itself naturally into three phases: the reaction itself, the recovery of methanol and other low-boiling materials, and vacuum evaporation of trace residues of volatile substances [17].

The BASF Process. The BASF process utilizes a continuous reactor equipped with a circulating pump and an external heat exchanger. Equimolar amounts of liquid methyl formate and gaseous ammonia [18] are introduced into the reactor [19], and the excess heat that results is removed by circulating the mixture over the external heat exchanger. Temperature is maintained in the range of 40 – 100 °C at 0.1 – 0.3 MPa. The gaseous phase is washed to remove excess ammonia and methyl formate. The inert gases methane, nitrogen, and a small amount of carbon monoxide (the latter arising as a decomposition product) are subsequently combusted together with off-gases from the evaporation step that also contain carbon monoxide. The reaction mixture, which consists of formamide, methanol, methyl formate, and ammonia then passes through a methanol recovery unit. This is a distillation system in which volatiles are isolated and separated into two fractions: methanol, and the low-boiling substances ammonia and methyl formate. Methanol accumulates at the bottom of the separator in sufficient purity to permit its use as a starting material in the synthesis of methyl formate. The low-boiling fraction contains virtually all the excess ammonia and methyl formate, together with a small amount of methanol, and this is recycled to the reactor. The residual formamide contains trace amounts of methanol which are removed under vacuum, leaving a product of sufficient purity to meet all standards applicable to both end-product and intermediate uses.

2.4. Environmental Protection

Flammability poses few problems, since formamide has very high ignition and flash points (>500 and 175 °C, respectively), as well as a low vapor pressure (see data in Section 2.1). Thus, the risk of combustion is quite low. If the substance should happen to ignite, the resulting fire may be quenched with water, extinguishing foam, carbon dioxide, or dry chemical extinguishers. Formamide should not be allowed to enter surface or groundwater sources but it can be readily biodegraded in appropriate wastewater treatment systems.

Serious effort should be made to prevent uncontrolled release of formamide from production and storage areas. The preferred method for transferring the liquid within an enclosed area involves the use of sealed pumps, although these should not be the stuffing-box type. Ideally, production should be carried out in the open, with exhaust gases washed or passed through a combustion unit prior to their release into the environment. If production or processing must be conducted within an enclosed facility, exceptionally good ventilation is essential because inhalation of formamide may be hazardous.

2.5. Quality Specifications and Analysis

Market demands require that formamide be available in a purity exceeding 99 %. The maximum permissible color number is 10 APHA, which implies a very low content of polymeric hydrocyanic acids and iron compounds. The material supplied by BASF is certified as meeting the following specifications.

Formamide content	min. 99.5 %	(by difference)
Methanol	max. 0.1 %	(photometric)
Ammonium formate	max. 0.1 %	(titrimetric)
Water content	max. 0.05 %	(DIN 51 777)
Iron	max. 1 ppm	(photometric)
Hazen color number	max. 10	(DIN 53 409)
pH	6.5	
Freezing point	≥2.1 °C	(DIN)

Methanol is determined photometrically after oxidation to formaldehyde, which in turn reacts with chromotropic acid to a purple dye. Ammonium formate content is measured by releasing the ammonia, trapping it with formaldehyde, and titrating the residual formic acid. The Karl Fischer method is employed for measuring water content. Iron is determined photometrically as the bipyridyl complex. The most accurate estimate of total formamide content results from subtracting the combined impurities from 100 %. Estimation by chromatography is less precise because of the compound's thermal instability, a consideration which also limits the usefulness of Kjeldahl determinations. Purity determination can also be based on melting point, which is related directly to the content of methanol and water.

2.6. Storage and Transportation

Unalloyed steel, copper, brass, and lead are all subject to corrosion by formamide, especially in the presence of water. Moreover, most protective paints and plastic coatings are attacked by the substance. In applications where iron contamination is undesirable aluminum and stainless steel containers are used instead of iron tanks. Formamide is shipped in containers made of stainless steel, in polyethylene drums, or in iron drums coated with polyethylene. Typical containers are designed to hold either 60 or 220 kg.

The physical and chemical properties of formamide are such that it is exempt from classification as a hazard with respect to highway, rail, inland waterway, or ocean transport.

When kept in closed containers, formamide is stable almost indefinitely. It is neither explosive nor subject to spontaneous combustion, although it is flammable. Those involved in the storage or transport of formamide should be familiar with the safety considerations discussed in Section 2.4, and Chapter 5.

2.7. Uses

Until relatively recently, the major application of formamide involved its reaction with sulfuric acid to produce formic acid and ammonium sulfate. However, alternative syntheses of formic acid based on methyl formate and water have now largely displaced the formamide method (→ Formic Acid, Chap. 4.). Currently, the principal application relates to the so-called formamide vacuum synthesis of hydrogen cyanide

[*74-90-8*] [20], in which formamide is pyrolyzed to hydrogen cyanide and water.

Formamide is also used as a synthetic intermediate in the preparation of various pharmaceuticals and fungicides. Examples include caffeine [*58-08-2*], theophylline [*58-55-9*], and theobromine [*83-67-0*] [21–24]. It serves as a catalyst in certain synthetic reactions, including carbonylation [25].

Formamide is employed widely as a *solvent*. It is used to dissolve lacquers [26] and plays a role in the spinning of acrylonitrile mixed polymerizates [27]. Together with nitromethane [*75-52-5*], it is used to dissolve polyacrylonitrile [*25014-41-9*] [28], and it is also employed in the polymerization of unsaturated amines to produce ion-exchange resins [29]. Formamide is a good solvent for wood stains, as well as for the ink used in felt- and fiber-tip pens. It was formerly employed in conjunction with silicates as a floor sealant, and also in de-icing airport runways, but these uses have been abandoned because of its teratogenic properties.

2.8. Economic Aspects

Only four major producers of formamide can be found worldwide. The leading manufacturer is BASF, with an annual capacity of 100 000 t in 1998. Most of the industrial output is utilized directly by the manufacturers. Despite the potential diversity of applications for formamide, market demand is relatively low, which explains why the number of production sites is so limited.

3. *N,N*-Dimethylformamide

3.1. Physical Properties

N,N-Dimethylformamide [*68-12-2*] (DMF), C_3H_7NO, M_r 73.09, is a colorless, high-boiling, nonviscous, highly polar, distillable, hygroscopic liquid with a weak, characteristically amine-like odor. Its most important physical characteristics can be summarized as follows:

mp	−61 °C
bp (at 101.3 kPa)	152.5 – 153.5 °C
Density ϱ (at 20 °C)	0.9500 g/cm^3
(at 50 °C)	0.9215 g/cm^3
Refractive index n_D^{20}	1.4310
n_D^{25}	1.4282
Dynamic viscosity η (at 15 °C)	0.87 mPa · s
(at 50 °C)	0.63 mPa · s
Surface tension σ (at 20 °C)	0.0355 N/m
Specific heat $c^{20}{}_p$	2062 J kg^{-1}K^{-1}
Thermal conductivity λ (at 40 °C)	0.180 Wm^{-1}K^{-1}
Heat of vaporization	573.5 kJ/kg
Heat of combustion	26 197 kJ/kg
Heat of formation (at 18 °C)	−3342 kJ/kg
Electrical conductivity (at 25 °C)	6×10^{-8} Ω^{-1} cm^{-1}
Dielectric constant (at 25 °C) (wavelength 1 – 5 m)	36
Dipole moment (at 20 °C)	3.82 D
Flash point (DIN 51 755)	58 °C
Ignition temperature (DIN 51 794)	410 °C
Explosive limits in air	2.2 – 16 vol %

Vapor pressure of DMF

t, °C	−50	−10	0	10	40	80	120	153
p, kPa	0.0003	0.033	0.081	0.182	1.34	9.67	42.0	101.3

Dimethylformamide is miscible in all proportions with water, alcohols, ethers, ketones, esters, and carbon disulfide, as well as with chlorinated and aromatic hydrocarbons. By contrast, it has only limited solubility or complete insolubilty in aliphatic hydrocarbons. Many high molecular mass natural products and synthetics are quite soluble in DMF. Examples include poly(vinyl alcohol) [*9002-89-5*], poly(vinyl chloride) [*9002-86-2*], poly(vinylidene chloride) [*9002-85-1*], poly(vinyl acetate) [*9003-20-7*] poly(vinyl ether), polyacrylate, polyacrylonitrile [*25014-41-9*], polystyrene [*9003-53-6*], polyester resins, alkyd resins, urea–formaldehyde resins, melamine – formaldehyde resins, phenol – formaldehyde resins, epoxy resins, and natural resins. It is also a good solvent for a number of drying oils, plasticizers, and cellulose derivatives, as well as for both natural and chlorinated rubber. The solubility of polyurethanes in DMF is a function of the conditions under which they are prepared. Most halogenated hydrocarbons are also soluble in DMF.

Various inorganic salts are highly soluble in DMF [30–38]. For example, the following solubilities (in 100 g DMF) are reported at 25 °C: 11.43 g of $FeCl_3$ [*7705-08-0*], 13.71 g of

Table 1. Solubility of organic gases in dimethylformamide (partial pressure 101.3 kPa)

Gas	CAS registry no.	Solubility (in 100 g of DMF), g 20 °C	100 °C
Vinylacetylene	[*689-97-4*]	112	18
Acetylene	[*74-86-2*]	5.1	0.9
1,3-Butadiene	[*106-99-0*]	11.2	2.5
Isobutene	[*115-11-7*]	7.3	1.5
Butane	[*106-97-8*]	4.7	1.3
Propene	[*115-07-1*]	0.78	0.46
Propane	[*74-98-6*]	0.85	0.33

KI [*7681-11-0*], 15.97 g of KSCN [*333-20-0*], 27.53 g of LiCl [*7447-41-8*], and 39.6 g of $NaClO_4$ [*7601-89-0*]. Several organic and inorganic gases are soluble in DMF, as indicated in Tables 1 and 2. Other gases such as ammonia, carbon monoxide, carbon dioxide, oxygen, and hydrogen dissolve in DMF to only a limited extent at atmospheric pressure.

Table 2. Solubility of inorganic gases in dimethylformamide (partial pressure 101.3 kPa)

Gas	Solubility (in 100 g of DMF), g at 25 °C
Hydrogen bromide	47.55
Hydrogen chloride	39.37
Hydrogen sulfide	1.32
Sulfur dioxide	179.00

3.2. Chemical Properties

N,*N*-Dimethylformamide is stable to air and light and, unlike its parent compound formamide, can be distilled without decomposition at atmospheric pressure. Nevertheless, decomposition is observed at temperatures above the boiling point, the products being carbon monoxide and *N,N*-dimethylamine. The compound also shows less tendency than formamide to hydrolyze. It is hygroscopic, however, and water absorbed from the air will produce traces of hydrolysis products; these produce the faint amine odor that frequently accompanies commercial DMF. The resistance of DMF to hydrolysis is demonstrated by the fact that a refluxing 5 % aqueous solution was found to have decomposed only 0.17 % after 120 h.

Pure DMF can be handled quite safely. Nevertheless, a few reports exist of reactions in which DMF displays a reactivity bordering on the explosive. Thus, with certain halogenated hydrocarbons, e.g., carbon tetrachloride or hexachlorobenzene, at elevated temperature and in the presence of ionic iron, explosive decomposition has occurred. Explosion during the reaction of DMF with thionyl chloride has also been described [39]. Furthermore elemental bromine and triethylaluminum [*97-93-8*] react violently with DMF. Vigorous oxidation reactions have been described in DMF systems containing chromic acid, as well as when nitrates are dissolved in DMF. Finally, DMF vapors form a flammable mixture with air.

3.3. Production

The first experiments directed toward the production of *N*-alkylformamides were conducted in the 19th century. Thus, A. Behal reported in 1899 that *N*-alkylformamides could be prepared by reacting mixed anhydrides of formic and other aliphatic acids with *N*- alkylamines. Since then, *N,N*-dimethylformamide has been synthesized by the reaction of hydrocyanic acid with methanol [40] or methylamines in the presence of water [41]. Other approaches include the reaction of ammonia or formamide with hydrogen and carbon dioxide in the presence of catalysts [42], as well as the reaction of *N,N*-dimethylamine with hydrogen and carbon dioxide [43]. Processes have also been described starting with carbon monoxide and *N,N*-dimethylamine, either alone [44] or together with trimethylamine [*75-50-3*] [45].

As with formamide, two methods dominate present-day commercial preparation of DMF: *direct synthesis* and a *two-step process.*

Direct Synthesis. The direct or one-step synthesis [46] of DMF begins with either pure carbon monoxide or a gas stream containing carbon monoxide. This is reacted in a continuous process with *N,N*-dimethylamine, by using a solution of alkali alkoxide (usually sodium methoxide) in methanol as catalyst. Methyl formate is presumably formed as an intermediate. The reaction mixture passes over an external heat exchanger to remove the excess heat generated and to ensure thorough mixing of the components [47].

The reaction is conducted between 0.5 and 11 MPa at 50 – 200 °C. The reaction mixture exits the reactor through a decompression chamber. In addition to *N,N*-dimethylformamide, the crude product contains methanol, a certain amount of unreacted *N,N*-dimethylamine, dissolved carbon monoxide, and residual catalyst. The addition of acid or water deactivates any catalyst present, resulting in the formation of sodium formate [*141-53-7*]. Dissolved carbon monoxide, together with inert gases, escapes from the mixture during decompression, and the off-gases are removed by combustion. Preliminary distillation is followed by a second distillation in a separate column; here, dimethylformamide is separated from methanol which contains traces of *N,N*-dimethylamine. Further distillation results in a product of 99.9 % purity.

Two-Step Process. The two-step process [48] for the synthesis of *N,N*-dimethylformamide differs from direct synthesis because methyl formate is prepared separately and introduced in the form of ca. 96 % pure (commercial-grade) material. Equimolar amounts of methyl formate and *N,N*-dimethylamine are subjected to a continuous reaction at 60 – 100 °C and 0.1 – 0.3 MPa. The resulting product is a mixture of *N,N*-dimethylformamide and methanol. The purification process involves distillation and is analogous to that described for direct synthesis. However, no separation of salts is required because no catalysts are involved in the process. According to the corrosive properties of both starting materials and products, stainless steel has to be used as material of construction for production facilities.

3.4. Environmental Protection

The physical properties of *N,N*-dimethylformamide (i.e., its autoignition temperature and flash point) are such that the compound is exempt from classification under the ordinance dealing with combustible liquids in the Federal Republic of Germany (VbF, Verordnung für brennbare Flüssigkeiten). If fire involving DMF does occur, it can be extinguished with water, dry chemical agents, or carbon dioxide.

N,N-Dimethylformamide is regarded as a hazardous liquid with respect to water pollution, and direct discharge into streams and lakes must be avoided. Nevertheless, it is easily biodegradable in appropriate wastewater treatment plants.

Regulations governing the use and disposal of *N,N*-dimethylformamide are essentially the same as those for formamide. The advisory covering atmospheric emissions in the Federal Republic of Germany (TA Luft, Verwaltungsvorschrift zum Bundesimmissionsschutzgesetz, 28th August 1974) places DMF in Category II. This means that DMF emissions exceeding 3 kg/h must be diluted to such an extent that the maximum concentration in air does not exceed 150 mg/m^3. If this limit cannot be met, the corresponding off-gases must be treated with water or combusted. The content of DMF in air can be measured either by gas chromatography or with an infrared detector.

3.5. Quality Specifications and Analysis

Most applications of DMF require that it be available in high purity. Table 3 contains the specifications applicable to DMF marketed by BASF.

The acid and base content of a DMF sample is established easily by potentiometric titration. The method of choice for determining DMF in an aqueous solution depends upon the anticipated concentration: those above 10 % may be quantified by gas chromatography, while lower concentrations are best measured with a double-beam infrared photometer. If only traces of DMF are expected, as in wastewater, a combination of chemical and physical methods of analysis

should be employed. Thus, any DMF present can be hydrolyzed with acid, after which the solution is made alkaline and the resultant *N,N*-dimethylamine is distilled. The latter is then converted to the corresponding nitroso compound, which can be determined polarographically. In the absence of impurities, DMF content can be calculated from simple physical measurements such as refractive index or density.

Table 3. Sales specifications for *N,N*-dimethylformamide from BASF

Sales specifications	Limit	Test method
DMF content	min. 99.9 %	gas chromatography
Methanol content	max. 100 mg/kg	gas chromatography
Water content	max. 0.03 wt %	DIN 51 777
Boiling range	152.5 – 153.5 °C	DIN 53 171
Acid content calcd. as HCOOH	max. 20 mg/kg	titrimetry
Base content calcd. as $NH(CH_3)_2$	max. 20 mg/kg	titrimetry
Hazen color no.	max. 10	DIN 53 409

3.6. Storage and Transportation

If it is pure and anhydrous, at ordinary temperatures, *N,N*-dimethylformamide does not tend to corrode metals during storage and transportation. Even with standard steel (ST 37), the linear corrosion rate for DMF is less than 0.01 mm per year. Exceptions to this generalization include copper, tin and their alloys.

Because DMF is hygroscopic, it readily absorbs moisture from the air, which renders it more corrosive. To prevent iron contamination, DMF should be packaged under an atmosphere of dry nitrogen if iron containers are used. To avoid all risk of contamination, it should be stored in stainless steel containers, although aluminum containers are recommended for DMF used in synthetic fiber production. Suitable gasket materials for pipelines, industrial fittings, and other apparatus exposed to DMF include poly(tetrafluoroethylene) [*9002-84-0*], high molecular weight polyethylene [*9002-88-4*], polypropylene [*9003-07-0*], and high molecular weight poly(vinyl alcohol) [*9002-89-5*]. *N,N*-Dimethylformamide may be shipped in tank cars, containers, and tank trucks fabricated from stainless steel. Iron drums with a capacity of 200 kg are also utilized. However, DMF should not be allowed to come in contact with chlorinated hydrocarbons because of the potential for explosive reaction, especially with such compounds as carbon tetrachloride [*56-23-5*] or hexachlorobenzene [*118-74-1*] in the presence of dissolved iron.

N,N-Dimethylformamide is subject to the following international transport designations (UN No. 2265):

Rail transport	GGVE/RID	3,32 C
Highway transport	GGVS/ADR	3,32 C
Water transport	GGVSee/IMDG-Gde	3,3
Air carriers	IATA-DGR/ICAO-TI	

Designations applicable to its transport and handling in the Federal Republic of Germany are derived from the ordinance "Verordnung über gefährliche Stoffe (Gefahrstoffverordnung GefStoffV)" of 26th August 1986, in which DMF is among the substances classified as having minimal toxicity. The corresponding designations include

Hazard symbol	Xn
R	20/21-36
S	26-28-36
EEC Guideline	616-001-00X

3.7. Uses

The principal applications of *N,N*-dimethylformamide are as a solvent and as an extractant, particularly for salts and compounds with high molecular mass. This role is consistent with its interesting combination of physical and chemical properties: low molecular mass, high dielectric constant, electron-donor characteristics, and ability to form complexes. The use of DMF as a component in synthesis is of relatively minor significance, at least commercially.

The most important use of DMF as a solvent for polymers is in the preparation of polyacrylonitrile solutions for the manufacture of fibrous polyacrylonitrile [*25014-41-9*], (→ Fibers, 4. Synthetic Organic, Chap. 5.). Residual DMF can be recovered from the spun fibers with relatively little expenditure of energy. In addition DMF is used as a solvent in the preparation of high-quality surfaces based on polyurethanes, which are otherwise difficult to solubilize, and it is employed as a solvent for coating surfaces with polyamides.

The high boiling point and high solvating power of DMF lead to its further use as a solvent for wire enamel formulated with polyamides, polyesterimides, or polyurethanes. Conversely, its solubilizing ability also makes it an effective component of paint removers, and it is used as a selective solvent in a wide range of manufacturing processes. For example, DMF is useful in separating acetylene from ethylene; butadiene from C_4 cuts; and hydrogen chloride, hydrogen sulfide, or sulfur dioxide from CO_2-containing gases. *N,N*-Dimethylformamide or mixtures containing it are used by oil refiners to extract aromatic compounds from hydrocarbon mixtures.

Table 4. Manufacturers of *N,N*-dimethylformamide

Manufacturer	Country	Annual capacity, t
Air Products	USA	7 000
BASF AG	Fed. Rep. of Germany	60 000
BASF	Brazil	6 000
Celanese	Mexico	6 000
Chinook	Canada	10 000
Du Pont	USA	40 000
Ertisa	Spain	5 000
ICI	UK	15 000
Korea Fertilizer Co.	Republic of Korea	8 000
LCY	Taiwan	10 000
Mitsubishi Gas Chemicals	Japan	20 000
Nitto Chemicals	Japan	25 000
UCB	Belgium	16 000
VEB Leuna	German Democratic Republic	19 000

Solutions of salts in specially purified DMF serve as fillers for electrolytic capacitors, a role made possible by the high dielectric constant of DMF. This substance is also used either alone or with other solvents in the recrystallization of aromatics, heterocyclics, dyes, fluorescent whitening agents, and pigments. The pharmaceutical industry also utilizes its broad solvent and extractant properties

N,N-Dimethylformamide could potentially be employed in the synthesis of aldehydes, acetals, amides, amidines, esters, and heterocycles, but thus far its use has been limited [49–53].

3.8. Economic Aspects

N,N-Dimethylformamide is produced by a number of manufacturers worldwide; total capacity is estimated at 250 000 t per year. Much of the production is utilized directly by the manufacturers, the most important of whom are listed in Table 4.

The principal market for DMF is as a solvent for polyacrylonitrile, followed by its use in processing polyurethanes. The remaining applications are remarkably diverse but minor relative to the principal uses.

4. Other Formamides

While many other *N*-substituted formamides are known, only three have achieved a measure of commercial significance; *N*-methylformamide, *N*-formylmorpholine, and formanilide. These are prepared by a two-step process: either the corresponding nitrogen compound is reacted with methyl formate, or a transamidation is performed, typically involving formamide.

***N*-Methylformamide.** *N*-Methylformamide [*123-39-7*], $HCONHCH_3$, M_r 59.1, is a colorless, nearly odorless liquid that is infinitely soluble in water and relatively stable to hydrolysis at low temperature. Commercial material is available with a purity of at least 99.7 %. Its most important physical properties include the following: *mp* −3.2 °C; boiling range 199.3 – 200.5 °C; ϱ (at 20 °C) 1.003 g/cm^3; n_D^{20} 1.432 – 1.433; flash point 111 °C; ignition temperature 425 °C; explosive limits in air 3.8 – 17.8 vol %; vapor pressure (at 20 °C) 0.014 kPa (0.14 bar). The substance is used as an intermediate in the synthesis of the insecticide formothion. It also has limited use in oil refineries as a selective solvent for aromatic hydrocarbons.

***N*-Formylmorpholine.** *N*-Formylmorpholine [*4394-85-8*], $HCON(CH_2)_4O$, M_r 115.13, is a colorless liquid with a faint amine-like odor. It is very resistant to hydrolysis at low temperature and has sufficient thermal stability to be distilled at atmospheric pressure. Commercial material has a minimum purity of 99.5 %. The following are important physical properties of this substance: *mp* 20 – 21 °C; *bp* 244 °C; ϱ (at 20 °C) 1.152 g/cm^3; n_D^{20} 1.4870; flash point 125 °C; ignition temperature 370 °C; explosive

limits in air 1.2 – 8.5 vol %; vapor pressure (at 80 °C) 0.17 kPa.

N-Formylmorpholine is used by petroleum refiners as a solvent for the extraction of aromatics and also as an anticorrosive agent in fuel oil.

Formanilide. Formanilide [*103-70-8*]; $HCONHC_6H_5$, M_r 121.14, is used as an intermediate in the pharmaceutical industry and as an antioxidant (anti-ager) in the rubber industry.

Formamides containing various aliphatic substituents on nitrogen have acquired limited significance as solvents and extractants. Thus, *N,N*-di-*n*-butylformamide [*761-65-9*] or *N*-methyl-*N*-2-heptylformamide [*68018-42-8*] can be used to extract organic acids from aqueous media [53].

5. Toxicology and Occupational Health

Formamide.

Acute Toxicity. Acute toxicity studies demonstrate that single doses of formamide, administered by a variety of routes, have low toxicity. In rats the acute *oral* LD_{50} is >5000 mg per kilogram body weight [55], [56] and the acute dermal LD_{50} is 13.5 g per kilogram body weight [56]. The acute inhalation hazard is low: no mortality was observed in rats exposed for 8 h at 20 °C to an atmosphere enriched in or saturated with formamide [55]. In the rabbit skin and eye the substance is not irritating to slightly irritating [55], [56]. Skin sensitization was not observed in guinea pigs [57].

Subacute, Subchronic Toxicity. Twenty oral doses of 300 µL formamide per kilogram body weight, given to rats via stomach tube, over four weeks were lethal in 50 % of the animals. The affected organs were the stomach, spleen thymus, adrenals, and testis. Treatment with 100 µL per kilogram body weight resulted in reduction of body weight gain and a reduced food intake whereas 30 µL per kilogram body weight did not produce any observable adverse effects [58]. Rats were subjected to doses of 30 – 3000 mg per kilogram body weight, applied dermally for three months (6 h per day, 5 d per week), semi-occlusive on the intact skin. Mortality occurred after treatment with 3000 mg per kilogram body weight. The affected organs were the liver, kidney, adrenals, spleen and testis. Hematological investigation revealed polycytemia, a change in the red blood picture, as the only effect observed. This effect also occurred at doses of 1000 and 300 mg/kg but not at 100 and 30 mg/kg body weight [59].

Mutagenicity. In several mutagenicity tests on bacterial systems (Ames test [60–62]), on mammals (dominant lethal test, mouse [64]), or in an in vitro short term test for carcinogenic activity (cell transformation test in rat embryo cultures [64], [65]) formamide did not demonstrate a mutagenic potential.

Teratogenicity. Formamide has been tested in a variety of studies for its teratogenic effects. In rats and mice the compound produced adverse effects on the offspring after oral and dermal administratation. The degree of fetal damage depends on the stage of pregnancy at which the substance was given. Doses that had adverse effects on the dams also had distinct effects on the offspring; at lower doses the effects were less pronounced [56], [66].

TLV Value. The TLV value (1988 – 1989) was established to be 10 ppm (15 mg/m^3).

Dimethylformamide.

Acute Toxicity. Dimethylformamide which has been tested in different animal species using various administration methods is slightly toxic. The affected organs, especially after repeated administration are the liver and kidney.

The acute *oral* LD_{50} in rats and mice is 2200 – 7550 mg per kilogram body weight [67–69]. The acute *dermal* LD_{50} in rats is between 800 and 17 000 mg per kilogram body weight and in rabbits between 1000 and 5000 mg per kilogram body weight. The acute inhalative LC_{50} in rats is given as >2500 ppm for a four or six hour exposure and 2475 ppm for a one-hour exposure [69]. In mice LC_{50}-values are 9.4 mg/L (3133 ppm, two-hour exposure) or 686 ppm (two-hour exposure) [56]. Rats survived a four-hour inhalation of an atmosphere

enriched or saturated with DMF at room temperature, but deaths occurred after 6 h [67]. In other studies cats, rabbits, guinea pigs, and rats survived an eight-hour exposure to a saturated atmosphere without any adverse effects. Rabbits, cats, and dogs survived a 6 h-inhalation of 1000 ppm [67].

Irritation. DMF slightly irritates the rabbit skin. The liquid is absorbed by the skin and can facilitate the absorption of other substances [56], [67]. The compound has a pronounced irritating effect on the eye of rabbits, the effects being reversible within 14 d [56], [67], [69]. Washing the eye with water immediately after application increased the irritating effect and produced opacity of the cornea [69]. Although DMF has not been shown to cause sensitization [67], a case of allergic contact dermatitis has been reported [70].

Subacute and Subchronic Toxicity. In subacute and subchronic animal studies (rats, mice, rabbits, cats, and dogs) in which repeated doses of DMF were given orally, dermally, or by inhalation, nephrotoxicity and hepatotoxicity were the prominent effects. The doses and concentrations used varied widely depending on the method and duration of administration. Changes in the red blood picture were observed in a few cases (for further details, see [56], [67]).

Mutagenicity. DMF has been investigated in several mutagenicity tests covering all different end points of mutagenic activity and has in all these tests been found to be non-mutagenic [56].

Carcinogenicity. Animal studies published so far have not provided any evidence of carcinogenicity [56]. Rats receiving 150 mg DMF per kilogram body weight in their drinking water for 500 d did not develop tumors. A weekly subacute treatment with doses of 200 or 400 mg per kilogram body weight (total dose 8 – 20 g per kilogram body weight) did not increase the incidence of tumor rate in the rat. A single intraperitoneal injection of 0.5 g per kilogram body weight to rats with or without simultaneous partial hepatectomy did not cause formation of tumors or "nodules" as early stages. In an insufficiently designed, inadequately described study, rats developed multiple tumors, liver necrosis, and ulceration of the intestinal mucosa after ten weekly intraperitoneal injections of 1 mL per rat. In comparison to all other mentioned studies the latter result seems to be inadequate.

Teratogenicity. DMF has been tested in different animal species for its adverse effects on the offspring using various administration methods. Fetotoxic and embryotoxic effects (fetal death and/or reduced fetal weight) were observed, especially at doses that produced toxic effects in the dams. In some studies DMF increased the incidence of malformations.

Oral doses that are toxic to the dams increased the incidence of malformations in rats and rabbits, whereas lower doses which were not maternally toxic are still embryotoxic [71], [72]. In mice oral administration of DMF leads to embryotoxicity and to an increase in the incidence of spontaneous malformations without detectable maternal toxicity [72]. Dermal application of DMF (200 mg kg^{-1} d^{-1}) in the rabbit caused fetal death; maternal toxicity was not discussed [73]. Other investigators found that dermal administration of a 200 mg kg^{-1} d^{-1} dose of DMF, applied semi-occlusively, did not have any effects in rats but a dose of 400 mg kg^{-1} d^{-1} increased the incidence of skeletal anomalies and showed slight maternal toxicity [72]. In other studies in rats, dermal application of DMF at doses which were slightly toxic to the dams had adverse effects on the offspring [72], [73]. In inhalation studies, embryotoxic effects were observed in rats at doses that produced maternal toxicity; in a few cases these effects already occurred in the absence of maternal toxicity [56].

Dermal administration of 400 mg kg^{-1} d^{-1} caused a higher incidence of anomalies in the offspring of rabbits, parallelled by reduced body weight in the dams. The next lower dose of 200 mg kg^{-1} d^{-1} did not cause any effects [74].

Inhalative exposure of rabbits (6 h/d, 7 – 19 day of pregnancy) to a DMF concentration of 150 and 450 ppm in the respiratory air produced dose-dependent maternal toxic, embryotoxic, and teratogenic effects. A concentration of 50 ppm did not cause any effects [75]. According to these investigations DMF seems to be teratogenic after inhalation only in higher concentrations which normally also lead to observable maternal toxicity. The threshold concentration for embryotoxic and teratogenic effects after inhalative exposure is between 50 – 150 ppm.

MAK Value. The MAK value is established to be 20 ppm (60 mg/m^3) refering to the danger of skin resorption.

1. Introduction

Formic acid [*64-18-6*] HCOOH, M_r 46.03, is a colorless liquid with a pungent odor, which is completely miscible with water and many polar solvents but only partially miscible with hydrocarbons. Formic acid derived its name from the red ant, *Formica rufa*, in which it was discovered around 1670. Formic acid has been detected in the poison or defense systems of ants, bees, and other insects and also of cnidarians.

Formic acid is used primarily in dyeing, in the textile and leather industries; in rubber production; and as an intermediate in the chemical and pharmaceutical industries. The use of formic acid as an aid in the ensilage of green forage has increased sharply.

The worldwide production of formic acid is about 260 000 t/a in 1987 and 390 000 t/a in 1995 [1]. Formic acid is produced by hydrolysis of methyl formate or formamide or from its salts. In addition, formic acid is a byproduct of acetic acid production by liquid-phase oxidation of hydrocarbons.

2. Physical Properties

Formic acid, *mp* 8.3 °C [2], *bp* 100.8 °C (at 101.3 kPa) [3], is a colorless, clear, very corrosive liquid with a pungent odor. With a pK_a of 3.739, formic acid is the strongest unsubstituted fatty acid, about ten times stronger than acetic acid [4]. Pure formic acid is hygroscopic.

The temperature dependence of the *density* of formic acid is given in Table 1. The density of formic acid – water binary mixtures, as a function of formic acid concentration, is shown in Table 2.

Table 4 shows the *vapor pressure* curve of pure formic acid. The vapor of formic acid deviates considerably in behavior from an ideal gas because the molecules dimerize partially in the vapor phase. At room temperature and normal pressure, 95 % of the formic acid vapor consists of dimerized formic acid [8]:

The enthalpy of the gas-phase dimerization is −63.8 kJ/mol [8]. The thermodynamic properties of monomeric and dimeric formic acid have been investigated by Waring [9].

Table 4. Vapor pressure of pure formic acid [7]

Liquid		Solid	
t, °C	p, kPa	t, °C	p, kPa
−5.23	1.083	−5.07	0.664
0.00	1.488	0.00	1.096
8.25	2.392	8.25	2.392

59.98	25.693		
70.04	37.413		
79.93	52.747		
100.68	101.667		
110.62	135.680		

The ring-type dimeric structure exists both in the vapor phase and in solution. Liquid formic acid consists of long chains of molecules linked to each other by hydrogen bonds. Solid formic acid can also be isolated in two polymorphic forms (α and β) [10]:

Portion of the chain in an α-type formic acid crystal

Portion of the chain in a β-type formic acid crystal

The thermodynamic properties of monomeric and dimeric formic acid have been investigated [10].

Vapor – liquid equilibrium data for formic acid – water mixtures and for mixtures of formic acid with organic compounds have been collected in [11]. Formic acid and water form a maximum-boiling azeotropic mixture whose boiling point is 107.6 °C at 101.3 kPa; it consists of 77.6 wt % formic acid and 22.4 wt % water. The composition and boiling point of formic acid – water azeotropic mixtures are shown as a function of pressure in Table 5. Formic acid can form azeotropic mixtures with many other substances [14].

Table 5. Azeotropic data for the formic acid – water system

p, bar	bp of azeotropic mixture, °C	Formic acid content, wt %	Reference
0.093	48.6	66.2	[12]
0.267	72.3	70.5	[12]
1.013	107.6	77.6	[12]
2.026	128.7	84	[13]
3.140	144	85	[13]

The variation of dynamic *viscosity* with temperature is shown in Table 6. The dynamic viscosity of formic acid – water mixtures decreases approximately linearly as the water content of formic acid increases [15]. The *thermal conductivity* of formic acid is markedly higher than that of comparable liquids, because of its pronounced polarity.

Table 6. Dynamic viscosity of pure formic acid as a function of temperature [16]

t, °C	η, mPa · s
10	2.262
20	1.804
30	1.465
40	1.224
50	1.025

The variation of specific *heat capacity* with temperature is shown in Table 7. The specific heat capacity of formic acid – water mixtures decreases approximately linearly as the concentration of formic acid increases [6].

Table 7. Specific heat capacity of formic acid as a function of temperature at constant pressure [17]

The physical properties of formic acid are listed below:

Heat of fusion		276 J/g [7]
Heat of vaporization (at bp)		483 J/g [7]
Dielectric constant		
Liquid (at 20 °C)		57.9 [21]
Solid (at −10.1 °C)		11.7
Refractive index n_D^{20}		1.37140 [19]
Surface tension σ		
(at 20 °C)		37.67×10^{-3} N/m [20]
(at 40 °C)		35.48×10^{-3} N/m
(at 60 °C)		33.28×10^{-3} N/m
(at 80 °C)		31.09×10^{-3} N/m
Heat of formation ΔH_f^0		
Liquid	(at 25 °C)	−425.0 kJ/mol [22]
Vapor	(at 25 °C, monomer)	−378.57 kJ/mol [8]
	(at 25 °C, dimer)	−820.94 kJ/mol
Heat of combustion ΔH_c^0		
Liquid	(at 25 °C)	−254.8 kJ/mol [22]
Entropy S^0		
Liquid	(at 25 °C)	129.0 J K^{-1} mol^{-1} [10]
Vapor	(at 25 °C, monomer)	248.88 J K^{-1} mol^{-1} [8]
	(at 25 °C, dimer)	332.67 J K^{-1} mol^{-1} [8]
Heat of neutralization		56.9 kJ/mol [23]
Critical data p_{crit}		7.279 MPa [18]
	T_{crit}	581 K [18]
	ϱ_{crit}	0.392 g/cm^3 [18]
Thermal conductivity λ		
Liquid	(at 20 °C)	0.226 W m^{-1} K^{-1} [18], [24]
	(at 60 °C)	0.205 W m^{-1} K^{-1}
	(at 100 °C)	0.185 W m^{-1} K^{-1}
Vapor	(at 50 °C)	0.0136 W m^{-1} K^{-1}
	(at 100 °C)	0.0176 W m^{-1} K^{-1}
	(at 200 °C)	0.0267 W m^{-1} K^{-1}
Electrical conductivity (at 25 °C)		6.08×10^{-5} Ω^{-1} cm^{-1} [25]
Coefficient of cubic expansion α (at 30 °C)		0.001 [3]

In 1968, GALLANT reported the important physical properties of formic acid and other low molecular weight fatty acids as a function of temperature [18].

3. Chemical Properties

To some extent, formic acid reacts differently from its higher homologues because it is both a carboxylic acid and an aldehyde.

Aldehyde Reactions. In some reactions, formic acid behaves like an aldehyde. Thus if an aqueous solution of formic acid is heated with a silver nitrate solution, metallic silver is deposited. Mercury, gold or platinum ions are reduced in solution, as are organic compounds. For

example, formic acid reduces triphenylmethanol to triphenylmethane. The reduction of imines (Schiff bases) by formic acid has been known for a long time. Primary amines can be prepared from ketones, ammonia, and formic acid (Leuckart reaction). Like other aldehydes, formic acid has bactericidal properties.

Carboxylic Acid Reactions. Magnesium, zinc, and iron dissolve in formic acid with the evolution of hydrogen. Because of its strongly acidic nature, many alcohols can be esterified by formic acid, without the addition of mineral acids. Primary and secondary alcohols are esterified in pure formic acid 15 000 – 20 000 times more rapidly than in pure acetic acid [26]. The rate of esterification of primary, secondary, and tertiary alcohols in formic acid has been determined [27], [28]. Because of its extremely reactive carboxyl group, amines can be formylated by formic acid, with high yields, for example, the yield of *N*-methylformanilide [*93-61-8*] is 93 – 97 %. Formic acid adds to the double bonds of olefins to form esters. Acetylenes react with formic acid in the vapor phase to yield vinyl formates [29].

Formic acid may also be used as a source of carbon monoxide. Thus, carboxylic acids can be prepared from olefins and formic acid in the presence of sulfuric or hydrofluoric acid (Koch carboxylic acid synthesis). Formic acid and tertiary organic bases form addition compounds (3 : 1 and 2 : 1 ratio of formic acid : base). If, for instance, 1 mole of gaseous triethylamine is passed in 3 moles of anhydrous formic acid, the addition product is obtained in quantitative yield. In these compounds formic acid is present in an extremely active form. Addition compounds of formic acid and trimethylamine or triethylamine can be used as liquid reducing agents in many selective reductions. The reduction of sulfur dioxide to sulfur is approximately quantitative [30].

Formic acid reacts with hydrogen peroxide in the presence of an acidic catalyst to form unstable performic acid [*107-32-4*] (HCOOOH); performic acid (→ Peroxy Compounds, Organic) may decompose explosively when heated to 80 – 85 °C. Performic acid exhibits typical peroxide properties [31]. The reactions of formic acid were summarized by Gibson in 1969 [32].

Although formic acid is not very stable, it can be distilled at atmospheric pressure in the absence of catalysts. Formic acid may decompose into either carbon monoxide and water (dehydration) or carbon dioxide and hydrogen (dehydrogenation); the nature of the decomposition and the reaction rate depend strongly on the presence of catalysts, the temperature, and the concentration of formic acid. *Dehydrogenation* is catalyzed preferentially by metals (platinum sponge, copper, nickel, silver). *Dehydration*, on the other hand, is catalyzed by aluminum oxide, silicon dioxide, and charcoal. Dehydration is promoted by mineral acids but inhibited by water; it also occurs on activated metal surfaces which must be considered during the preparation and processing of formic acid, as well as during transportation and storage of the highly concentrated acid. Tables 8 and 9 show the formation of carbon monoxide as a function of formic acid concentration and temperature [33]. A summary of the catalytic decomposition of formic acid has been published by Mars [34], along with an extensive list of references. The temperature dependence of formic acid decomposition at low temperature (between 40 – 100 °C) has been investigated [35].

Table 8. Volume of carbon monoxide produced per liter of formic acid (99 wt %) as a function of storage time and temperature [33]

Time, *d*	*V*, L		
	at 20 °C	at 30 °C	at 40 °C
15	0.012	0.064	0.303
30	0.024	0.128	0.597
60	0.049	0.255	1.161
90	0.073	0.381	1.700

Table 9. Volume of carbon monoxide produced per liter of aqueous formic acid as a function of storage time and concentration [33]

Time, *d*	*V*, L ($t = 40$ °C)

60	0.039	0.437	1.161
90	0.058	0.653	1.700

4. Production

The worldwide installed capacity for producing formic acid was about 330 000 t/a in 1988. The installed formic acid processes can be classified in four groups:

1) methyl formate hydrolysis,
2) oxidation of hydrocarbons,
3) hydrolysis of formamide, and
4) preparation of free formic acid from formates.

The significance of individual processes has shifted considerably in the last decade because the economic data for production and raw products have changed and new processes have been developed. In the past, a large amount of the formic acid utilized was a byproduct in the manufacture of acetic acid. However, the proportion of formic acid produced by dedicated processes has increased.

Formic acid is a byproduct in the production of acetic acid [*64-19-7*] by liquid-phase oxidation of butane or naphtha (→ Acetic Acid, Chap. 4.2.). For many years, oxidation of hydrocarbons was the most important method of producing acetic acid. Over the past decade, however, the preferred process in the establishment of new acetic acid plants has been the carbonylation of methanol [36], which is expected to remain the preferred method in the future. As a result, the proportion of formic acid produced worldwide, which results as a byproduct in the manufacture of acetic acid, will continue to decrease.

The production of formic acid by hydrolysis of formamide [*75-12-7*] played an important role in Europe; in 1972, about one-third of the world production was obtained by this process [3]. However, the consumption of ammonia and sulfuric acid, along with the unavoidable production of ammonium sulfate, have in many cases made this process economically inferior. As a result, the direct hydrolysis of methyl formate is currently preferred.

Another industrial production method involves formation of the free acid from its salts. Sodium formate [*141-53-7*] and calcium formate [*544-17-2*] are used for this purpose.

The economic disadvantages of the methods discussed led to the development of a process specifically dedicated to the production of formic acid, with no undesirable byproducts. In the 1970s, the hydrolysis of methyl formate [*107-31-3*] to methanol and formic acid was developed commercially by various firms into an economically feasible method. This process involves carbonylation of methanol and subsequent hydrolysis of the methyl formate produced. The methanol resulting from this process is returned to the first stage. Formic acid plants based on this process were started up at BASF (Federal Republic of Germany) in 1981 and Kemira (Finland) in 1982 [37]. Most of the formic acid plants begun in recent years employ this principle of methyl formate hydrolysis.

Table 10 shows the world capacity for various formic acid production processes in 1986. Although other methods for producing formic acid have been patented, they do not appear to have been implemented industrially. Direct synthesis of formic acid from carbon monoxide and water cannot be carried out economically because of the unfavorable position of the equilibrium.

Table 10. Formic acid production capacity in 1986 (without standby plants; BASF assessment)

Process	Capacity, t/a	Percentage of total capacity, %
Hydrolysis of methyl formate	160 000	49
Byproduct in hydrocarbon oxidation	74 000	22

In recent years, various ways of producing formic acid from carbon dioxide and hydrogen have been investigated extensively, but this method has not yet been applied industrially. The oxidation of methyl *tert*-butyl ether [*1634-04-4*] with oxygen to form *tert*-butyl formate [*762-75-4*] and formic acid has been described [38]. Various methods have been developed for the electrochemical production of formic acid, but they have not been used commercially [3], [39]. The combined production of formic acid and acetic acid from methyl formate, carbon monoxide, and water with methyl iodide [*74-88-4*] as promoter and anhydrous rhodium chloride [*13569-65-8*] as catalyst, has been described by BP [40].

4.1. Methyl Formate Hydrolysis

Synthesis of formic acid by hydrolysis of methyl formate is based on a two-stage process: in the

first stage, methanol is carbonylated with carbon monoxide; in the second stage, methyl formate is hydrolyzed to formic acid and methanol. The methanol is returned to the first stage:

$$CH_3OH + CO \longrightarrow HCOOCH_3$$

$$CH_3OOCH + H_2O \longrightarrow CH_3OH + HCOOH$$

$$CO + H_2O \longrightarrow HCOOH$$

Although the carbonylation of methanol is relatively problem-free and has been carried out industrially for a long time [3], [41], only recently has the hydrolysis of methyl formate been developed into an economically feasible process. The main problems are associated with work-up of the hydrolysis mixture. Because of the unfavorable position of the equilibrium, reesterification of methanol and formic acid to methyl formate occurs rapidly during the separation of unreacted methyl formate. Problems also arise in the selection of sufficiently corrosion-resistant materials.

Older publications suggest the reaction of methyl formate and a dicarboxylic acid, with subsequent distillation of formic acid from the higher-boiling esters [3]. Degussa suggested hydrolyzing methyl formate at 200 °C above atmospheric pressure and then reducing the pressure suddenly to less than 0.1 MPa. Separation of the methyl formate–methanol mixture flash-evaporated from the aqueous formic acid can then take place in a liquid separator [5].

Industrial methods involving carbonylation of methanol and hydrolysis of methyl formate, followed by isolation of the formic acid, were developed by (1) the Leonard Process Company (United States), (2) BASF (Federal Republic of Germany), (3) Halcon – Scientific Design – Bethlehem Steel (United States), and (4) the Scientific Research Institute for the Chlorine Industry of the Ministry of the Chemical Industry (former Soviet Union).

Key patents relating to the carbonylation of methanol and the hydrolysis of methyl formate are listed in [43].

Basic Principles. *Carbonylation of Methanol*. In the four processes mentioned, the first stage involves carbonylation of methanol in the liquid phase with carbon monoxide, in the presence of a basic catalyst:

$$CH_3OH + CO \longrightarrow HCOOCH_3 \quad \Delta H_R^0 = -29\ \text{kJ/mol}$$

This reaction was first described by BASF in 1925 [41]. As a rule, the catalyst is sodium methoxide [*124-41-4*]. Potassium methoxide [*865-33-8*] has also been proposed as a catalyst; it is more soluble in methyl formate and gives a higher reaction rate [44]. Although fairly high pressures were initially preferred, carbonylation is carried out in new plants at lower pressure. Under these conditions, reaction temperature and catalyst concentration must be increased to achieve acceptable conversion. According to published data, ca. 4.5 MPa, 80 °C, and 2.5 wt % sodium methoxide are employed. About 95 % carbon monoxide, but only about 30 % methanol, is converted under these circumstances. Nearly quantitative conversion of methanol to methyl formate can, nevertheless, be achieved by recycling the unreacted methanol. The carbonylation of methanol is an equilibrium reaction, and Table 11 specifies the equilibrium concentrations of methyl formate.

Table 11. Maximum methyl formate concentration (in weight percent) achievable by carbonylation of methanol (unpublished BASF data)

t, °C	p, MPa			
	1	5	9	17
50	59	95	98	99
60	43	91	96	99
70	31	85	94	98
80	21	78	90	96
90	15	69	85	94
100	10	59	79	91
110	7	49	71	87
120	5	39	62	82

The reaction rate can be raised by increasing the temperature, the carbon monoxide partial pressure, the catalyst concentration, and the interface between gas and liquid:

$$r = C \cdot a \cdot e^{-E/RT} \cdot c \cdot p_{CO}$$

where

r = reaction rate,
C = proportionality coefficient,
a = interface between gas and liquid,
E = activation energy,
R = molar gas constant,
c = catalyst concentration in solution, and
p_{CO} = CO partial pressure in the gas phase [45].

This equation reveals the dependence of reaction rate on the partial pressure of carbon monoxide. Therefore, to synthesize methyl formate, gas mixtures with a low proportion of carbon monoxide must first be concentrated; this can be achieved by low temperature distillation, pressure-swing adsorption, prism separators (Monsanto), or the Cosorb process (Tenneco).

In a side reaction, sodium methoxide reacts with methyl formate to form sodium formate and dimethyl ether, and becomes inactivated:

$$NaOCH_3 + HCOOCH_3 \longrightarrow HCOONa + CH_3OCH_3$$

The substances used must be anhydrous; otherwise, sodium formate is precipitated to an increasing extent:

$$NaOCH_3 + H_2O + HCOOCH_3 \longrightarrow 2\,CH_3OH + NaOOCH$$

Sodium formate is considerably less soluble in methyl formate than in methanol. The risk of encrustation and blockage due to precipitation of sodium formate can be reduced by adding poly(ethylene glycol) [46]. The carbon monoxide used must contain only a small amount of carbon dioxide; otherwise, the catalytically inactive carbonate is precipitated.

Basic catalysts may reverse the reaction, and methyl formate decomposes into methanol and carbon monoxide. Therefore, undecomposed sodium methoxide in the methyl formate must be neutralized [47].

Hydrolysis of Methyl Formate. In the second stage, the methyl formate obtained is hydrolyzed:

$$HCOOCH_3 + H_2O \rightleftarrows CH_3OH + HCOOH \qquad \Delta H_R^0 = 16.3\ \text{kJ/mol}$$

The equilibrium constant for methyl formate hydrolysis depends on the water: ester ratio [48]. With a molar ratio of 1, the constant is 0.14, but with a water: methyl formate molar ratio of 15, it is 0.24. Because of the unfavorable position of this equilibrium, a large excess of either water or methyl formate must be used to obtain an economically worthwhile methyl formate conversion. If methyl formate and water are used in a molar ratio of 1 : 1, the conversion is only 30 %, but if the molar ratio of water to methyl formate is increased to 5 – 6, the conversion of methyl formate rises to 60 %. However, a dilute aqueous solution of formic acid is obtained this way, and excess water must be removed from the formic acid with the expenditure of as little energy as possible.

Another way to overcome the unfavorable position of the equilibrium is to hydrolyze methyl formate in the presence of a tertiary amine, e.g., 1-(*n*-pentyl)imidazole [*19768-54-8*], [49]. The base forms a salt-like compound with formic acid; therefore, the concentration of free formic acid decreases and the hydrolysis equilibrium is shifted in the direction of products. In a subsequent step formic acid can be distilled from the base without decomposition.

A two-stage hydrolysis has been suggested, in which a water-soluble formamide is used in the second stage [50]; this forms a salt-like compound with formic acid. It also shifts the equilibrium in the direction of formic acid.

To keep undesirable reesterification as low as possible, the time of direct contact between methanol and formic acid must be as short as possible, and separation must be carried out at the lowest possible temperature. Introduction of methyl formate into the lower part of the column in which lower boiling methyl formate and methanol are separated from water and formic acid, has also been suggested. This largely prevents reesterification because of the excess methyl formate present in the critical region of the column [51].

The hydrolysis of methyl formate is catalyzed by strong acids, but the efficiency of strong mineral acids [52] is restricted because they also promote the decomposition of formic acid. In the processes described by BASF, Leonhard, and Halcon – Scientific Design – Bethlehem Steel, autocatalysis by formic acid is therefore used. In the Soviet Union, a process has been described in which hydrolysis is carried out in a vertical column reactor divided into two zones [53]; the upper zone is filled with a strongly acidic cation exchanger which partially hydrolyze methyl formate. In the lower part of the reactor, hydrolysis is carried out with autocatalysis by formic acid produced in the upper section.

Dehydration of the Hydrolysis Mixture. Formic acid is marketed in concentrations exceeding 85 wt %; therefore, dehydration of the hydrolysis mixture is an important step in the production of formic acid from methyl formate. For dehydration, the azeotropic point must be

overcome. The concentration of formic acid in the azeotropic mixture increases if distillation is carried out under pressure (Table 5), but the higher boiling point at high pressure also increases the decomposition rate of formic acid. At the same time, the selection of sufficiently corrosion-resistant materials presents considerable problems. A number of entrainers have been proposed for azeotropic distillation [43].

BASF describes various energy-saving processes for the dehydration. One process involves extractive distillation with *N*-formylmorpholine [*4394-85-8*] [54]. Another method of increasing formic acid concentration in dilute solutions without a considerable input of energy is to extract formic acid from water by liquid – liquid extraction. Secondary amides have been proposed [55] as extractive agents. Formic acid binds weakly to the amide; therefore, water can be distilled to overcome the azeotropic point. In a subsequent column, formic acid can then be distilled from the extractant in vacuo. The energy consumed can be reduced further by optimizing the exchange of heat [56].

4.1.1. Kemira – Leonard Process

A 20 000-t/a formic acid plant based on a method developed by the Leonard Process Co. [57] was built at Kemira in Finland and put into operation in 1982. The process has been developed further by Kemira, and licences for it have been issued in Korea, India and Indonesia.

In the Kemira – Leonard process, Methyl formate and carbonylation is carried out at about 4 MPa and a temperature of approximately 80 °C, with additive-containing alkoxides used as catalyst [58]. Hydrolysis is carried out in two reactors with different operating conditions. Methyl formate and water react in the preliminary reactor in approximately equimolar proportions. The formic acid produced catalyzes the hydrolysis in the main reactor. An excess of methyl formate is employed in the main reactor, and hydrolysis is carried out at ca. 120 °C and 0.9 MPa. The reactor discharge is brought to atmospheric pressure in a flash tank; reesterification is largely prevented by the cooling that occurs during flash-evaporation. methanol are separated under vacuum. Although the reverse reaction is attenuated further as a result, condensation of the low-boiling methyl formate in vacuo presents a problem. The formic acid is dehydrated by distillation. If 85 wt % formic acid is desired, dehydration must be carried out at ca. 0.3 MPa. Even higher concentrations can be achieved by connecting an additional dehydration column downstream under atmospheric pressure, and formic acid concentrations up to ca. 98 wt % can then be drawn off as the distillate.

Process Description [57–60] (Fig. 1). Compressed carbon monoxide and methanol are converted into methyl formate in reactor (a). Catalyst is fed into the reactor in a methanol solution. The amount of methanol introduced in this way makes up for methanol losses in the process. The discharge from reactor (a) is flashed and fed into the methyl formate column (b) from which methyl formate is drawn off as the distillate. Methanol and the dissolved catalyst are returned to the reactor; inactivated catalyst (primarily sodium formate) is crystallized and discharged.

Off-gas from column (b) and waste gas from reactor (a) are burned. Methyl formate reacts partially with water in the preliminary reactor (c), and discharge from the preliminary reactor is fed into the main reactor (d) along with recycled methyl formate, methanol, and water. The contact time in this reactor is largely sufficient for equilibrium to be established. Reactor discharge is flashed to approximately atmospheric pressure in the flash tank (e); methyl formate, methanol, and small quantities of formic acid evaporated in this process are recycled to the main reactor (d). Methyl formate and methanol are distilled in vacuo in the acid separation column (g). Contact time is minimized by internals with a small liquid holdup. The distillate is separated into methyl formate and methanol in the recycle column (f). Formic acid can be concentrated under pressure in a column; if the pressure is ca. 0.3 MPa, 85 % formic acid is drawn off as the bottom product. Distillation in two columns is more industrially controllable. Water is distilled overhead in the first product column (h). The bottom product is concentrated further in the second product column (i), and formic acid with a maximum concentration of ca. 98 wt % is drawn off as distillate. The bottom product is recycled to the first product column.

4.1.2. BASF Process

A 100 000-t/a formic acid plant began operating in Ludwigshafen (Federal Republic of Germany) in 1981. In this plant, a technology for the hydrolysis and dehydration was used for the first time.

The production of methyl formate by carbonylation of methanol has been carried out on a large scale for many years at BASF [41], [61]. The carbonylation stage is largely identical to that of the Kemira – Leonard process, but the hydrolysis stage and the dehydration of formic acid are noticeably different.

In the BASF process, hydrolysis is carried out with a large excess of water (about 5 mol of water per mole of methyl formate) to shift the equilibrium in the direction of formic acid. Much of the water is separated by liquid – liquid extraction with a secondary amide.

Process Description (Fig. 2) Carbon monoxide and methanol react in the methyl formate reactor (a) in the presence of sodium methoxide. Methyl formate is fed, as a distillate, from the methyl formate column (b) into the formic acid reactor (c) together with recycled methyl formate. Methanol and dissolved catalyst are drawn off from the bottom of column (b) and returned to reactor (a); catalyst decomposition products are discharged by crystallization. In reactor (c), methyl formate is hydrolyzed with excess water at elevated temperature and increased pressure. The reaction product is flashed into the low-boiler column (d). Methyl formate is removed as the distillate, with methanol as a side stream, and dilute aqueous formic acid is drawn off from the bottom into the extraction unit (e). Here, the formic acid and some of the water are extracted by the secondary amide. Most of the water (largely free of formic acid) is recycled to reactor (c). The extract–a mixture of extractant, formic acid, and some water–is distilled in the dehydration column (f). Enough water is distilled via the head for the required formic acid concentration to be obtained in the pure acid column (g). This column is operated in vacuo. The extraction agent is recycled from the bottom of column (g) to the extraction unit.

4.1.3. USSR Process

A 40 000-t/a formic acid plant based on a process [53] developed in the former Soviet Union is being built in Saratov (Ukraine) [62] and is expected to be operational in 1989.

According to published material, this formic acid process differs from the above-mentioned processes [63], [64] in the hydrolysis stage. Hydrolysis is carried out at 80 °C and 0.6 MPa in a fixed-bed reactor equipped with bubble-cap trays in the upper section. Reesterification is prevented by decompressing and cooling to about 45 °C. Formic acid is produced in a pressure column as an azeotropic mixture with water which contains 85 wt % formic acid.

Process Description [63], [64] (Fig. 3). Carbon monoxide reacts with methanol in column reactor (a), in the presence of the catalyst and a stabilizer, at about 3 MPa, to yield methyl formate. Separation into methyl formate (distillate) and methanol plus catalyst takes place in the methyl formate column (b) at 0.2 MPa. The exhaust gas produced is partially recycled. In reactor (c), methyl formate is hydrolyzed with water in two stages; in the first stage, packed acidic cation exchanger is used as catalyst (f), which partially hydrolyzes the methyl formate. In the second stage, hydrolysis is carried out with autocatalysis by the formic acid produced in stage one. Methanol and methyl formate are distilled from the hydrolysis product in the low-boiler column (d); these compounds are separated, along with the carbonylation reaction mixture, in the methyl formate column (b). Aqueous formic acid is drawn off the bottom of column (d) and further dehydrated in the formic acid column (e) under pressure. Formic acid with a content of 85 wt % is drawn off in the side stream, and the concentration can be increased to about 98 wt % in the column situated downstream.

4.1.4. Scientific Design – Bethlehem Steel Process

The process developed jointly by Scientific Design and Bethlehem Steel [65] has not yet been implemented industrially on a large scale.

The carbonylation stage is essentially similar to the processes described previously. If the concentration of carbon monoxide is higher than 90 mol %, a single back-mixed reactor is provided, but if the carbon monoxide concentration is between 50 and 90 mol %, a two-stage, countercurrent, back-mixed reactor system is recommended. If the carbon monoxide concentration

Figure 3. Production of formic acid (USSR process)
a) Methyl formate reactor; b) Methyl formate column; c) Hydrolysis reactor; d) Low-boiler column; e) Formic acid column; f) Fixed-bed catalyst

is low, however, the total pressure must be increased considerably [66]. The hydrolysis is catalyzed by formic acid, and the dehydration is carried out by distillation alone.

4.2. Other Processes

4.2.1. Oxidation of Hydrocarbons

Formic acid is produced as a byproduct in the liquid-phase oxidation of hydrocarbons to acetic acid (→ Acetic Acid, Chap. 4.2.). In the United States, butane [*106-97-8*] is used as the hydrocarbon, and ca. 50 kg of formic acid is produced per ton of acetic acid. In Europe, the oxidation of naphtha is preferred, and up to 250 kg of formic acid is produced per ton of acetic acid in this process. For the mechanism of formic acid production, see [59].

Unreacted hydrocarbons, volatile neutral constituents, and water are separated first from the oxidation product. Formic acid is separated in the next column; azeotropic distillation is generally used for this purpose. The entrainers preferred in this process are benzene or chlorinated hydrocarbons. The formic acid contains about 2 wt % acetic acid, 5 wt % water, and 3 wt % benzene [59]. Formic acid with a content of about 98 wt % can be produced by further distillation.

4.2.2. Hydrolysis of Formamide

In 1972, 35 % of the formic acid produced worldwide was still made by the formamide process developed by BASF. However, because of the direct hydrolysis of methyl formate, this process has lost much of its significance (see Table 10).

Formic acid is produced this way in a three-stage process. In the first stage, methanol is carbonylated to yield methyl formate:

$$CO + CH_3OH \rightarrow HCOOCH_3 \qquad \Delta H_R^0 = -29\ \text{kJ/mol}$$

In the second stage, formamide is produced by ammonolysis of ethyl formate:

$$HCOOCH_3 + NH_3 \rightarrow HCONH_2 + CH_3OH \qquad \Delta H_R^0 = -72\ \text{kJ/mol}$$

In the third stage, sulfuric acid is used to hydrolyze formamide to formic acid and ammonium sulfate:

$$HCONH_2 + 1/2\,H_2SO_4 + H_2O \longrightarrow HCOOH + 1/2\,(NH_4)_2SO_4 \qquad \Delta H_R^0 = -48\ \text{kJ/mol}$$

Methanol is carbonylated as in the first stage of the processes already described (Section 4.1). Conversion to formamide is usually carried out at 0.4 – 0.6 MPa and 80 – 100 °C; methanol is distilled and recycled to the methyl formate stage (see → Formamides). Formamide is hydrolyzed continuously in the third stage by using 68 – 74 % sulfuric acid at temperatures between 85 °C and the boiling point of formic acid [3]. This reaction is carried out preferably in stirred containers and provides the heat for the distillation of formic acid. A hot slurry consisting essentially of ammonium sulfate and formic acid flows out of the stirred container into a rotary kiln where the residual formic acid is distilled so that dry, pure ammonium sulfate is produced at the kiln end. The yield of formic acid exceeds 90 %. The economic efficiency of this process is determined by the commercial value of ammonium sulfate.

Hydrochloric acid, nitric acid, or phosphoric acid can also be used to hydrolyze formamide [3].

4.2.3. Production of Formic Acid from Formates

The reaction of sodium formate [*141-53-7*] or calcium formate [*544-17-2*] with strong mineral acids, such as sulfuric and nitric acids, is the oldest known process for producing formic acid commercially. If formates or sodium hydroxide are available cheaply or occur as byproducts in other processes, formic acid can still be produced economically in this manner.

Formates as Byproducts in the Production of Polyhydric Alcohols. Sodium formate and calcium formate occur as byproducts in the production of pentaerythritol [*115-77-5*], trimethylolpropane [*77-99-6*], and 2,2-dimethyl-1,3-propanediol [*126-30-7*] (neopentyl glycol) (→ Alcohols, Polyhydric). The formates unavoidably produced in this manner are used in several plants as feed for manufacturing formic acid.

Formates from Sodium Hydroxide and Carbon Monoxide. The production of sodium formate from sodium hydroxide and carbon monoxide once had considerable significance, but today this process is carried out simply to utilize excess sodium hydroxide solution in low-capacity plants. The economic efficiency of producing formic acid from its salts suffers because one equivalent of a low-value inorganic salt (e.g., sodium sulfate), is produced per mole of formic acid.

Carbon monoxide reacts with alkaline compounds, even in aqueous solution, to yield the corresponding formates:

$$CO + NaOH \xrightarrow{H_2O} HCOONa$$

Carbon monoxide is mixed countercurrently with aqueous sodium hydroxide, for example, in a tower reactor at 1.5 – 1.8 MPa and 180 °C [59]. Sodium formate crystallizes and reacts with strong mineral acids, (e.g., concentrated sulfuric acid) at normal pressure in a cooled, stirred reactor at 35 °C:

$$2\,HCOONa + H_2SO_4 \rightarrow 2\,HCOOH + Na_2SO_4$$

The reaction mixture is separated, for example, in a thin-film evaporator at normal pressure and 100 – 120 °C, to produce formic acid and dry sodium sulfate [67]. The suggestion has been made that reaction with sulfuric acid be carried out in two stages. In this case, the first stage takes place in vacuo in a horizontal tubular reactor with rotating internals, and some of the formic acid is evaporated at the same time. In the second stage, the remaining formic acid is evaporated, also in vacuo, at 30 – 60 °C in a smaller tubular reactor [68].

Norsk Hydro describes the production of formic acid from calcium formate by reaction with nitric acid. The calcium nitrate produced may be used, for example, as a fertilizer.

4.2.4. Direct Synthesis from Carbon Monoxide and Water

The simplest theoretically possible method of producing formic acid is to react carbon monoxide with water:

$$H_2O + CO \rightleftarrows HCOOH$$

As pressure increases and temperature decreases, the equilibrium of this exothermic reaction shifts in favor of formic acid. Below 150 °C, the reaction rate is very slow, and although equilibrium is reached rapidly at higher temperature, the pressure must be increased drastically to obtain acceptable formic acid concentrations. Table 12 lists the calculated equilibrium concentrations at various temperatures and pressures.

Inorganic acids and salts have been described as catalysts in the literature. Unless the reaction rate can be increased markedly by the development of new catalysts, direct synthesis cannot be used for the economical production of formic acid.

Table 12. Calculated equilibrium concentrations of formic acid at different temperatures and pressures [69]

Carbon monoxide pressure, MPa			Formic acid concentration, wt %
at 25 °C	at 100 °C	at 217.9 °C	
0.027	0.63	6.95	1
0.30	7.15	79.1	10
0.72	16.95	187	20
3.7	85.8	950	50
108	2540	28170	90

4.2.5. Use of Carbon Dioxide

Interesting developments in carbon dioxide chemistry have resulted in formic acid syntheses, but so far these have not been used industrially [70].

Zinc selenide [*1315-09-9*] and zinc telluride [*1315-11-3*] have been proposed as catalysts for the hydrogenation of carbon dioxide [71]. If homogeneous transition-metal catalysts are employed, carbon dioxide, hydrogen, and water can be converted to formic acid. If alcohol is used instead of water, the corresponding ester is produced. Ruthenium and palladium complexes have proved particularly active; either inorganic bases [72] or organic bases [73] (e.g., aliphatic tertiary amines) can be used as the alkaline material.

BP Chemicals has developed a process in which formic acid is produced from carbon dioxide and hydrogen via several process stages [74–76]. In the first stage, a nitrogen base such as triethylamine [*121-44-8*] reacts with carbon dioxide and hydrogen in the presence of a noble-metal catalyst (e.g., a ruthenium complex) to yield the formate of the nitrogen base. In the second and third stages, the formate is separated from the catalyst and the low-boiling constituents. In the fourth stage, the formate reacts with a high boiling base, for example, 1-(*n*-butyl)imidazole [*4316-42-1*], to yield a formate that can be thermally decomposed. Simultaneously, the low-boiling base is liberated and distilled. In the fifth stage, the formate is thermally decomposed, formic acid distilled, and the high-boiling base is returned to the fourth stage.

4.3. Concentration of Formic Acid

Formic acid – water mixtures cannot be concentrated to more than the azeotropic composition by simple distillation (→ Distillation and Rectification). Further dehydration is carried out by ternary azeotropic distillation, extractive distillation, or extraction. Additional concentration can then be achieved by simple distillation. Through suitable choice of distillation conditions, formic acid with a content exceeding 99 wt % can be drawn off as distillate.

Azeotropic Distillation. Propyl and butyl formates have been proposed as entrainers for azeotropic distillation [3]. A particularly economical separation of water from the water – formic acid – acetic acid mixture obtained by oxidizing butane is achieved by azeotropic distillation with ethyl *n*-butyl ether [*628-81-9*] [77].

Extractive Distillation. In extractive distillation, formic acid is extracted in a distillation column by means of a basic extracting agent introduced countercurrently and fed into the bottom of the column. If this mixture is heated in a column downstream, the formic acid is liberated from the salt-like compound and distilled. *N*-Formylmorpholine [*4394-85-8*] has been suggested as extractant [54], and various sulfones have been described as auxiliary liquids for extractive distillation [78].

Extraction. A number of extractants have been proposed for extracting acetic and formic acids [79]. According to BASF, secondary amides are efficient extracting agents [55]; Hüls recommends compounds in the series tri-*n*-

octylamine [*1116-76-3*] to tri-*n*-dodecylamine [*102-87-4*] [80].

4.4. Construction Materials

The use of sufficiently corrosion-resistant materials in the individual process stages is part of the expertise of formic acid production. Tests on materials under laboratory conditions do not always guarantee that corrosion resistance can be achieved in practice. A low impurity content or a change in concentration or temperature may produce a decisive change in the corrosion resistance of a material toward formic acid.

If austenitic CrNi steels are used, those that contain molybdenum are preferred to molybdenum-free types [81]. Above 20 °C, stainless steel AISI 304 (Cr 18 wt %, Ni 8 wt %) has only adequate resistance, if the formic acid concentration is below 10 % or above 90 %. Stainless steel AISI 316 (Cr 18 wt %, Ni 10 wt %, Mo 2 wt %) is resistant up to ca. 50 °C to formic acid below 40 wt % or over 80 wt % [82]. For higher temperatures and formic acid concentrations between 40 and 80 wt %, steels with higher Cr, Ni, and Mo contents (for example, AISI 317 or 317 L) or special nickel-rich alloys must be used. Aluminum ist not sufficiently resistant to formic acid, except at concentrations below 30 wt % or above 80 wt % and at temperatures below 20 °C [82]. Titanium is resistant under oxidizing conditions but is attacked very strongly under reducing conditions [81]. The corrosion behavior of titanium is considerably improved by addition of platinum or palladium. The more exotic metals tantalum, niobium, and zirconium are also corrosion resistant [81].

Of the nonmetallic materials, graphite and glass are sufficiently corrosion-resistant, but their use is limited because of their poor mechanical properties. Among the common plastics, polyethylene is resistant up to about 50 °C. Polytetrafluorethylene (PTFE) and poly(vinylidene fluoride) (PVDF) are resistant to formic acid. Hard poly(vinyl chloride) (PVC) is resistant only at room temperature, and soft PVC should be used only for formic acid concentration below 10 wt %.

Liquid-crystal polymers (LCP) are recommended as packing materials for columns because their resistance to formic acid is reportedly much better than that of ceramics. A survey of construction materials used in formic acid production is given in [83].

5. Environmental Protection

Like most other simple organic acids, formic acid can be degraded rapidly and completely by biological methods. For this reason, formic acid is totally mineralized in a short time in purification plants and streams. The ecological equilibrium of the streams can, however, be disturbed by a change in pH. For formic acid, the theoretical biological oxygen demand (BOD) is 350 mg/g. The chemical oxygen demand has been determined to be 86 mg/g after 5 d (COD_5) and 250 mg/g after 20 d (COD_{20}). In the modified OECD screening test (OECD method 30 IE), formic acid is degraded to >90 % [84]. If an additional carbon source is available, degradation proceeds more quickly.

Toxicity to fish was tested on the blue gill sunfish (*Lepomis macrochirus*). The lethal dose (TLm 24) was found to be 175 ppm [85]. Toxicity in invertebrates was determined on *Daphnia magna*. The TLm 48 value was 120 ppm [86]. In the Federal Republic of Germany, formic acid is classified among the substances that slightly endanger water (Class 1 of water endangerment, WGK 1) [87].

Formic acid vapor can be removed from exhaust streams by washing with water. Fog results when formic acid vapor is emitted during periods of high humidity. In the Federal Republic of Germany emission is controlled by the technical guidelines for air (TA Luft) [88]. Formic acid belongs to Class 1, which means that for emission rates of 0.1 kg/h or higher, the formic acid concentration must be <20 mg/m^3 in the exhaust gas. Upon filling of formic acid, the displaced air is recycled via a gas-transfer line or it is emitted after purification (e.g., by water washing or passage through an incinerator).

6. Quality Specifications

Formic acid is marketed in concentrations of 85, 90, 95, 98, and >99 wt %. The impurity content depends on the production process. Formic

acid produced by oxidation of hydrocarbons still contains a small proportion of acetic acid. A typical specification for formic acid produced by hydrolysis of methyl formate is given in Table 13; this acid meets the specifications required in the Food Chemicals Codex (FCC) [90].

Table 13. Sales specification for formic acid [89]

Specification	Limits	Analytical method
Content	min. 85 wt % min. 90 wt % 99 wt %	titrimetric, ISO 731/II, 5.2
Color number	max. 10 APHA	ASTM D 1209-79
Acetic acid	max. 150 mg/kg	ISO 731/VII
Sulfate	max. 1 mg/kg	ISO 731/V
Chloride	max. 1 mg/kg	ISO 731/IV
Iron	max. 1 mg/kg	ISO 731/VI
Other heavy metals	max. 1 mg/kg	FCC III
Evaporation residue	max. 20 mg/kg	DIN 53 172
Quality	the formic acid complies with DAB 7 and FCC III	

7. Chemical Analysis

The concentration of formic acid is normally determined by titration with sodium hydroxide solution. Volatile impurities can be determined by gas chromatography on packed columns. Polyesters or Carbowax 20 M, both treated with phosphoric acid and adsorbed on chromosorb as a carrier, have proved successful as the stationary phase. Formic acid content is measured with a thermal-conductivity cell because the substance cannot be detected with flame ionization detectors (FID).

Test methods for formic acid have been standardized by the International Organization for Standardization (ISO) [91]. Other standard analytical methods for formic acid are described in [92].

8. Storage and Transportation

Formic acid is stored in tanks made of austenitic CrNi steels (18 % Cr, 10 % Ni, 2 % Mo), for example, AISI 316 L. The use of other materials, such as AISI 304 L, polyethylene-lined carbon steel, glass-lined carbon steel, and polypropylene, is restricted to specific concentrations and low temperatures. Tank cars and tank trucks made of AISI 316 L are used for transportation. Small canisters may be made of polyethylene; glass bottles are used for laboratory quantities. When aqueous formic acid mixtures are stored or transported the melting points at various concentrations (Table 3) should be considered. Tanks are best heated with hot water or subsidiary electrical heating systems. To prevent corrosion, even of AISI 316, wall temperatures above 50 °C must be avoided. Formic acid decomposes to highly toxic carbon monoxide and water. For this reason, formic acid with a concentration of 99 wt % or higher is transported in canisters without gastight seals [3]. Containers of highly concentrated formic acid should be protected against exposure to heat and stored in a well-ventilated place. Before entering ship tanks or storage tanks that have contained highly concentrated formic acid, personnel should monitor the carbon monoxide content of the air. The storage method should ensure that contact with strong alkali solutions (evolution of heat) and strong acids or oxidizing agents (decomposition) does not occur. Table 14 contains important safety data.

9. Legal Aspects

Formic acid is marked according to the regulations of the European Economic Community (council directive 76/907/EEC including the latest amendment) and to the regulations of the Federal Republic of Germany (Gef Stoff V) [94] as: Corrosive, R34 (formic acid content 25 – 90 wt %), R35 (formic acid content > 90 wt %), and S 2-23-26. The EEC numbers of formic acid are 607-001-00-0 (formic acid content >90 wt %) and 607-001-01-8 (formic acid content 25 – 90 wt %). Hazard classifications for the transport of formic acid are listed in the following:

RID/ADR	class 8, item 32 b
Fed. Rep. of Germany: GGVE/GGVS	class 8, item 32 b
ADNR	class 8; item 21 b
IMDG Code (Fed. Rep. of Germany: GGVSee)	8
IATA-DGR	1779
UN Number	1779
DOT Hazard Classification (USA)	corrosive material
HazChem Code (UK)	2 R

Table 14. Safety data [93] for formic acid

	Formic acid content, wt %				
	85	90	94	99	Method
Flashpoint, °C	59	58	55	48	DIN 51 755
Autoignition point, °C	500	480	480	480	DIN 51 794
Flammable limits in air, vol %	15 – 47	14 – 44	14 – 38	12 – 38	

10. Uses

Because of its acidity, its aldehyde nature, and its reducing properties, formic acid is used in a variety of fields (Table 15).

Table 15. Applications of formic acid (1988, BASF assessment)

Textiles, leather	25 %
Pharmaceuticals, crop-protection agents	10 %
Latex, rubber auxiliaries	10 %
Silage	35 %
Miscellaneous	20 %

In contrast to mineral acids, formic acid evaporates without leaving any residue. The leather and textile industries, in particular, make use of its strongly acidic nature. Animal skins and hides are acidified with a mixture of formic acid, sulfuric acid, and sodium chloride before chrome tanning (→ Leather).

Formic acid is used for adjusting the pH of dye baths in dyeing of natural and synthetic fibers. Use is made of its highly reactive nature in the manufacture of pharmaceuticals and crop-protection agents [32], [43]. Formic acid plays an important role in the coagulation of rubber latex.

In Europe, most of the formic acid is used as a silage aid. If freshly mown, damp grass is sprayed with formic acid to establish a pH of ca. 4, such fodder can be used directly for silage. Formic acid promotes the fermentation of lactic acid and suppresses the harmful formation of butyric acid. If formic acid is used, fermentation processes occur more rapidly and at lower temperature so that fewer nutrients are lost [95], [96]. Mixtures of formic acid with formaldehyde or with ammonium formate are also used as silage aids. Silage that utilizes formic acid is restricted largely to Europe, but it should be of interest in all regions where climate makes *green forage* difficult to dry.

Other applications of formic acid are as an additive for cleaning agents (replacement of mineral acid for environmental reasons), in the synthesis of the sweetener aspartame [*22839-47-0*] [97] (→ Amino Acids, Chap. 5.1.2.), and in the desulfurization of flue gas by the Saarberg – Hölter process (pH stabilization of the wash liquid) [98]. A large potential market for formic acid is anticipated by the Leonard Process Co. in steel pickling and wood pulping [58]. In both fields, however, formic acid has not yet replaced the standard techniques (steel pickling with hydrochloric acid or wood pulping by the Kraft process).

Table 16. Worldwide formic acid production capacity (BASF assessment)

Company	Basis of process	Capacity, t/a
BASF (Fed. Rep. of Germany)	methyl formate	100 000
BP (UK)	naphtha	50 000
Kemira Oy (Finland)	methyl formate	40 000
Norsk Hydro (Norway)	calcium formate	13 000
Chem. Werke Hüls (Fed. Rep. of Germany)	sodium formate	10 000
Perstorp (Sweden)	sodium formate	10 000
Far (Italy)	sodium formate	10 000
CSSR	formamide	10 000
Celanese (United States)	butane	13 000
PT Pupuk Kujang (Indonesia)	methyl formate	10 000
GNFC (India)	methyl formate	5 000
Korea Fertilizer (Republic of Korea)	methyl formate	5 000
Daicel (Japan)	naphtha	5 000
Others	sodium formate calcium formate formamide	50 000
Under construction or planned (start-up):		
USSR	methyl formate	40 000 (1989)
USSR	methyl formate	40 000 (1990)

11. Economic Aspects

A breakdown of production capacity for formic acid is given in Table 16.

12. Derivatives

Among the derivatives of formic acid, amides (→Formamides), various esters, and salts are the most important.

12.1. Esters

Esters of formic acid have the typical physical and chemical properties of esters; they are readily volatile and flammable, and have a sweet, often fruity smell. They are only partially soluble in water. A summary of their chemical properties has been published by GIBSON [32].

12.1.1. Methyl Formate

Methyl formate [*107-31-3*], $C_2H_4O_2$, M_r 60.05, is an intermediate in the production of formic acid (Sections 4.1, 4.2) and formamide (→ Formamides, Chap. 2.3.) in large manufacturing plants. With increasing interest in the production of synthesis gas by coal gasification, methyl formate will become important as a versatile key intermediate. It can also be used as a starting material in the production of high-purity carbon monoxide [99]. Physical properties, safety data, and marking regulations for methyl formate are summarized below.

Boiling point (101.3 kPa)	31.7 °C [17]
Melting point	−99 °C [17]
Specific gravity d_4^{20}	0.975 [17]
Refractive index n_D^{20}	1.3433 [99]
Flash point (open cup)	−20 °C [99]
Ignition temperature	450 °C [99]
Flammable limits in air	5.0 – 23 vol % [99]
MAK value	100 mL/m^3; 250 mg/m^3 (category I)
TLV–TWA	100 mL/m^3; 250 mg/m^3
TLV–STEL	150 mL/m^3 ; 375 mg/m^3
UN number	1243
EEC number	607-014-00-1
Marking according to Gef Stoff V (FRG)	symbol : F R12, S 9-16-33
Hazchem Code (UK)	2 SE
RID/ADR	class 3, item I a
ADNR	class 3, item I a
IMDG Code (F.R. of Germany GGVSee)	3.1
IATA-DGR	1243
DOT Hazard Classification (USA)	flammable liquid

Production. Methyl formate is produced by base-catalyzed carbonylation of methanol (Section 4.1). Processes have been developed for dehydrogenating methanol, but these have not yet been implemented commercially [100]:

$$2\,CH_3OH \longrightarrow HCOOCH_3 + 2\,H_2 \quad \Delta H_R^0 = 98.9\,\text{kJ/mol}$$

Catalysts containing copper are used.

Mitsubishi Gas Chemical (MGC) has developed highly active catalysts which contain Cu – Zr – Zn or Cu – Zr – Zn – Al. The conversion of methanol is approximately 50 %, with a methyl formate selectivity of ca. 90 % and a space – time yield of 3000 g L^{-1} h^{-1} [101]. Air Products uses a copper – chromite catalyst for the dehydrogenation of methanol [102]. Methyl formate can also be produced by oxy-dehydrogenation of methanol:

$$2\,CH_3OH + O_2 \longrightarrow HCOOCH_3 + 2\,H_2O \quad \Delta H_R^0 = -472.8\,\text{kJ/mol}$$

Soluble chromium compounds are used as catalyst [103].

The direct synthesis of methyl formate from synthesis gas has been investigated:

$$2\,CO + 2\,H_2 \longrightarrow HCOOCH_3 \quad \Delta H_R^0 = -157.2\,\text{kJ/mol}$$

The high pressure of 100 – 200 MPa (1000 – 2000 bar) required makes economical implementation impossible [100]. The dimerization of formaldehyde has likewise not been exploited industrially [100]:

$$2\,CH_2O \longrightarrow HCOOCH_3 \quad \Delta H_R^0 = -146.4\,\text{kJ/mol}$$

Uses. Most of the methyl formate produced is used as an intermediate for the production of formic acid and formamide. Dimethylformamide [*68-12-2*] is produced by reacting methyl formate with dimethylamine [*124-40-3*] (→ Formamides, Chap. 3.3.). A new use has been found for methyl formate in the production of foundry molds. The mold is formed from granular refractory material and a binder consisting of phenol – formaldehyde resin which is cured by exposure to methyl formate vapor. This process makes possible the production of rapidly cured foundry molds at low temperature [104].

Small quantities of methyl formate are used as solvents and insect control agents. With the anticipated extension of C_1 chemistry, methyl formate may be used as an intermediate for a number of products [99], [100].

12.1.2. Ethyl Formate

Ethyl formate [*109-94-4*], $C_3H_6O_2$, M_r 74.08, *bp* 54.1 °C, *mp* −80 °C, $d_{4^0}^2$ 0.923, flash point −20 °C, ignition point 440 °C, UN number 1190, has a sharp rumlike smell and taste.

Ethyl formate is produced by carbonylation of ethanol with carbon monoxide or by esterification of ethanol with formic acid.

Ethyl formate is a solvent for acetyl cellulose and nitrocellulose. Ethyl formate is used in alcohol-free drinks, ice cream, chewing gum, and other confectionery as a component of apple-, pineapple-, banana-, and peach-type flavors.

12.1.3. Isobutyl Formate

Isobutyl formate [*542-55-2*], M_r 102.13, *bp* 98 °C, *mp* −96 °C, $d_{4^0}^2$ 0.88, flash point 5 °C, ignition point 320 °C, UN number 2393, is produced by carbonylation of isobutyl alcohol [*78-83-1*] with carbon monoxide or esterification of isobutyl alcohol with formic acid. Isobutyl formate is used as a solvent for colors, lacquers, adhesives, and cleansing agents.

12.1.4. Miscellaneous Esters

A number of formates produced by esterification of the corresponding alcohols with formic acid are used as perfumes and flavorings (→ Flavors and Fragrances). Some representative products are citronellyl formate [*105-85-1*], geranyl formate [*61759-63-5*], phenylethyl formate [*104-62-1*], benzyl formate [*104-57-4*], and isopentyl formate [*110-45-2*].

Orthoformates are used in the preparation of acetals and ketals. Chloroformic esters are used as intermediates in organic syntheses.

12.2. Salts

12.2.1. Alkali-Metal and Alkaline-Earth Metal Formates

Sodium formate [*141-53-7*] and calcium formate [*544-17-2*] are byproducts in the synthesis of polyols such as pentaerythritol. However, they are also produced directly from the corresponding hydroxides and carbon monoxide (Section 4.2.3) [3].

Sodium or calcium formate is used to produce formic acid (Section 4.2.3). An important process for manufacturing sodium dithionite [*7775-14-6*] starts with sodium formate. Oxalic acid [*144-62-7*] production employs sodium formate as an intermediate. Sodium formate is used in chrome tanning and as a mordant in the dyeing and printing of fabrics by the textile industry. The reducing power of sodium formate is utilized in electroplating baths and photographic fixing baths. Calcium formate is also used in tanning. Adding calcium formate to concrete reduces the setting time considerably.

12.2.2. Ammonium Formate

Ammonium formate solutions are used as a low-corrosion silage aid; the complex salts ammonium diformate [*64165-14-6*] and ammonium tetraformate [*70179-79-2*] are stable in aqueous solution [105].

12.2.3. Aluminum Formate

Stepwise replacement of the hydroxyl groups in aluminum hydroxide [*21645-51-2*] yields dibasic aluminum formate [*18748-09-9*], $(HO)_2Al(OOCH)$; Almonobasic aluminum formate [*51575-25-8*], $(HO)Al(OOCH)_2$; and aluminum formate [*22918-74-7*], $Al(OOCH)_3$. Aluminum hydroxy acetate formate [*34202-30-7*] $(HO)Al(OOCH)(OOCCH_3)$, is also manufactured commercially. The various formates are produced either directly from the metal or by reaction with an aluminum compound, for example, aluminum hydroxide [106].

uminum formates are used to impregnate textiles and to make paper water-resistant. Formates are also employed mordants in the textile industry. Because of the low toxicity and antiseptic, astringent, and basic properties of the aluminum salts, aluminum formates are used in pharmaceuticals.

12.2.4. Nickel Formate

Nickel(II) formate [*15694-70-9*] usually exists in the form of a green crystalline dihydrate

$Ni(HCOO)_2 \cdot 2\,H_2O$; it is prepared by dissolving nickel(II) hydroxide [*12054-48-7*] or nickel(II) carbonate [*16337-84-1*] in formic acid or by reaction of nickel(II) sulfate with sodium formate. Nickel(II) formate is used for the production of nickel hydrogenation catalysts.

12.2.5. Copper Formate (→ Copper Compounds , Chap. 5.1.)

Copper(II) formate [*544-19-4*] is produced by reacting copper(II) hydroxide [*20427-59-2*], copper(II) oxide [*1317-38-0*], or copper(II) carbonate [*12069-69-1*] with formic acid. It is used as an antibacterial agent for treating cellulose.

13. Toxicology and Occupational Health

Formic acid occurs naturally in small amounts in plants, animal poisons, and higher organisms. In humans, it is formed in toxic amounts during methanol poisoning. After intake of large amounts of methanol, the metabolic capacity to detoxify it to carbon dioxide is insufficient, and the high amount of formic acid that results leads to metabolic acidosis. Under physiological conditions, formic acid which is observed under these conditions in low concentration is a component of human blood and tissues, and plays an important role in the transfer of C_1 compounds during intermediate metabolism. Most of the formic acid taken up by the body is metabolized; a small portion is excreted unchanged in the urine. After oral intake, the biological half-life of formic acid is about 45 minutes in human blood plasma [107].

The most prominent toxic property of this compound is its corrosive effect upon skin and mucous membrane. When applied to the clipped skin of rabbits, formic acid causes necrosis, which heals slowly [108]. Following oral intake of aqueous dilutions of formic acid, corrosion of the oral cavity and esophagus occurs even at concentrations as low as 6 % [108–110]. The LD_{50} after oral administration is reported to be 1830 mg/kg in rats [111] and 1076 mg/kg in mice [112]. Formic acid, whose solubility in water is good, can be absorbed easily by the skin [107], [108] and causes serious local injuries upon inhalation. In rats, increasing concentrations of aqueous acid solutions, inhaled as saturated vapors (20 °C), lead to death during decreasing exposure times: a 10 % aqueous solution of formic acid is tolerated for 7 h. Eyelid closure and watery nasal discharge as a result of pronounced irritation is no longer observed after termination of the exposure period. A 25 % aqueous solution is lethal after an exposure of more than 3 h; a 50 % aqueous solution, after 30 min; and undiluted (98 %) formic acid, after only 3 min inhalation. In rats, the LC_{50} is 7.4 mg/L after inhalation of the vapor [113]. The predominant symptoms of inhalative intake are irritation of the eyes, irritation and corrosion of the nasal mucous membranes, and corneal opacity.

According to earlier investigations [108], formic acid affects the central nervous system (CNS). In rabbits, intravenous administration of buffered formic acid in the range of 0.46 – 1.25 g per kilogram of body weight leads to CNS depression; higher dosages cause convulsions. Subcutaneously administered doses of 0.8 g/kg in dogs and over 0.4 g/kg in cats lead to staggering, while a dosage of 0.4 g/kg leads to sleepiness in cats. In dogs, lethal doses administered intravenously result in tonic and clonic convulsions [108]. The mechanism of CNS effects was investigated by exposing rats to formic acid vapors (20 ppm) for 6 h a day, five days per week, for two or three weeks. This treatment caused changes in glial cell metabolism, which could be the reason for neurological effects [114].

Rats administered formic acid in concentrations of 0.5 and 1.0 % in feed and drinking water, respectively, showed a slight increase in body weight gain. In addition the weights of liver, kidneys, adrenals, and (for the lower dose group) spleen were lower than those of control animals [111]. In rats, the administration of dosages of 8.2, 10, 25, 90, 160, and 360 $mg\,kg^{-1}\,d^{-1}$ in drinking water for 2 to 27 weeks led to a lower intake of food and delay in body weight gain only in the highest dose group [115].

The influence of formic acid on biochemical parameters was investigated in rats by exposing them for 6 h a day to vapors of 20 ppm for three or eight days [116]. This treatment led to a decrease in the concentration of glutathione in the liver and kidneys.

Few experimental results are available regarding the mutagenic effects of formic acid. The substance was weakly mutagenic when tested on *Escherichia coli* [117]. A mutagenic effect was also observed on the germ cells of drosophila [118]. However, no primary genotoxic mechanism of action appears to be involved; rather, the mutagenicity is probably associated with the acidity of the compound, which leads to radical formation after inhibition of the enzyme catalase.

The TLV-TWA exposure limit (ACGIH) for formic acid is 5 ml/m^3 (9 mg/m^3); its MAK value is also 5 ml/m^3 (9 mg/m^3) (short term exposure maximum: category I). Formic acid has a PDK (former Soviet Union) of 0.5 ml/m^3 (1 mg/m^3).

1. Introduction

Casting is the formation of a solid body of predetermined size and shape (a casting) from a material without shape (a melt) by a process of cohesion (solidification in a mold). Foundry technology is the art and science of the processes and materials used in manufacturing castings from metals and alloys. It deals with the manufacture of molds and patterns, melting practice, metal treatment, and pouring methods, together with the processes for finishing castings (fettling) and the equipment used.

Most metallic materials may be formed by the casting process. To secure the properties required of the castings it is of crucial importance that the design is suitable for the casting process and that the metal is correctly chosen. The process is suitable for mass production of standard parts, as well as for small series and individual components.

History. The history of metal working and the extraction of metals from their ores goes back many thousands of years, although the earliest beginnings cannot be dated precisely. The oldest known castings date from about 3000 B.C. (copper alloys, lead, and tin bronzes). Around 1500 B.C. the technique of reducing iron ores was understood, and the lumps of iron so obtained were forged into artifacts. The casting of iron began in the late Middle Ages, steel casting became an industrial process in the 19th century, and now, in the 20th century, light metal casting is becoming of increasing importance [10–13].

There is continuous development of new alloys and casting techniques on the one hand and new mold-making methods and materials on the other. There are ever more stringent requirements, especially concerning mechanical properties of the castings, their surface quality, torsion resistance, and machinability, as well as lightweight construction, abrasion resistance, and suitability for series production. Tolerances become ever narrower (mass and physical properties), and quality control becomes increasingly elaborate and must include statistical procedures. Modern computer technology is now used in the entire foundry process, in design and planning, and in process and quality control. The impetus towards the development of new technology now comes not only from the need to compete with other materials and processes; occupational health and environmental aspects must also be considered.

2. The Casting Process

2.1. Fundamentals

Basically, foundry processes can be divided into two categories: casting of semi-finished products and casting of components (Fig. 1). Casting

10.1002/14356007.a12_035

Figure 1. Overview of casting processes

of semi-finished products can be further subdivided into continuous casting, ingot casting, strip and foil casting, melt spinning, rheocasting, crystal growth, spray casting, and powder spraying.

The most important process in industry is continuous casting. Continuous casting is the production of symmetrical solid or hollow profiles (billets, rods, tubes) by pouring the liquid metal into a water-cooled mold which determines its shape and from which it is extracted in a continuous or semi-continuous process. The profiles of continuously cast parts are usually given their final shape in subsequent forming processes. However, it is also possible to produce profiles directly. Strip, wire, and foil castings are also normally produced by continuous casting.

Component casting is used for the production of metal products with various specific contours and wall thicknesses. They are cast directly, as a liquid melt, into molds consisting of one or more parts. Cast components largely or completely meet the requirements for their final shape. The mold is a hollow form, the interior contours of which determine the shape of the casting, i.e., it is a negative of the desired casting. The processes for the casting of components can be further subdivided into nonpermanent- and permanent-mold methods.

Molding deals with the production of molds and cores; casting is concerned with the methods of filling the molds with molten metal. Molds and cores may be produced by machine or hand (individual parts).

Nonpermanent molds are generally made of sand or ceramics. After casting and cooling, the mold must be destroyed so that the casting may be removed. To produce the mold, a pattern (positive model of the casting) is needed. The molding material is applied to the pattern and set by compression or by hardening. The hollow space for the future casting is produced by pulling or lifting the pattern out of the mold. Hollow spaces within the casting itself are created by means of cores, produced in the same way as sand molds (Fig. 2).

The cores are placed onto previously prepared surfaces in the sand molds. (Different procedures used in investment casting and lost-foam

casting are described under these headings in Section 2.3.4) Patterns or coreboxes are made of wood, plastic, metal, or inorganic materials such as plaster. They can, if necessary be coated with abrasion-resistant coatings. The patterns may also be treated with release agents to facilitate their removal from the molding material.

Figure 2. Molding and casting with the hollow mold process and full mold processes [14]
A) Lower half of mold; B) Upper half of mold added; C) Pouring; D) Casting with flash; E) Foamed plastic pattern; F) Pattern in a one-piece box; G) Pouring, no cores; H) Casting without flash
a) Lower box (drag); b) Upper box (cope); c) Pattern plate; d) Core print; e) Riser; f) Ingate; g) Core with core irons; h) Flash

Permanent molds (dies) consist mainly of durable, heat-resistant metallic materials, usually special steel and cast-iron alloys that have undergone specific heat treatment. In permanent molds the hollow space for the future casting is created by machining, electrical-discharge machining, or by casting and subsequent machining. Permanent molds have the advantage that they can be used repeatedly from thousands to hundreds of thousands of times or more, depending on the cast alloy. Permanent molds often consist of several segments and have core pullers to allow even complex castings to be removed.

The casting processes, the cast alloys, and the weight limits which generally apply today are illustrated in Table 1. Castings range from only a few grams to several hundred tonnes in weight. Typical fields of application for castings are: the automobile industry; train, airplane, and ship building; the chemical industry; industrial furnaces; iron and steel works; foundries; energy production; the electrotechnical industry; precision engineering; transmission systems; construction and housing; mechanical engineering; and medicine [1], [8], [11], [15], [18], [34], [59–65], [105–111], [121–127].

2.2. Design of Castings

The design of a casting must be in accord with accepted standards and material information sheets. Choice of material, shape, mass, and other specifications, such as later surface finishing, are given in the technical drawing. This information is needed for designing the pattern, which must take into account the degree of shrinkage (see Section 3.2), degrees of taper, and machining allowances, as well as the position and type of cores and the arrangement of loose pieces (of pattern) necessary to form undercut parts of the mold. The pattern drawing also shows its position in the mold and the way in which it is usually divided into two parts, one for the upper molding box and one for the lower. At the same time the gating and, if required, feeding systems (see Section 3.2) are determined (Fig. 3).

In addition to the choice of suitable material and molding process, the design must be suitable for the actual process of casting so that both the manufacture and the desired physical and mechanical properties of the cast product are achieved. For this reason, the founder should participate in the design of the casting. It must not only be designed correctly as regards construction material and service requirements, but also be dimensionally accurate, clean, and able to pass the required tests.

Table 1. Range of application of the most common nonpermanent- and permanent-mold casting processes

Casting process	Casting alloys	Weight of casting	Series size
Hand molding	all cast alloys (mainly gray iron, ductile iron, steel, bronze)	up to over 100 t (limited only by melting and transport capacities)	individual parts, small series
Machine molding	all cast alloys (mainly gray iron, ductile iron, Al alloys)	1 kg to several tonnes	small and large series
Shell molding process	all cast alloys (mainly gray iron, ductile iron)	1 – 150 kg	medium and large series
Lost foam process	gray iron, ductile iron, steel, Al alloys	< 1 kg to several tonnes	individual parts, small and large series
Investment and precision casting	all cast alloys	1 g to100 kg	individual parts, small and large series
Gravity die casting	Al, Mg, Cu, Zn alloys; gray iron, ductile iron	< 1 kg to100 kg	medium and large series
Low- and counterpressure die casting	Al, Mg, Cu alloys	< 1 kg to 70 kg	medium and large series
Pressure die casting	Al-, Mg-, Cu-, Zn-,Sn-, and Pb-based pressure die casting alloys	several grams to 60 kg, depending on the alloy	medium and large series

Figure 3. Gating and feeding system for a hollow cylinder [2] (1981)

Modern near-net-shape production of components requires close cooperation between designer and foundryman to reduce costs, aftertreatment, and weight. In addition, all the possibilities offered by the casting process must be taken advantage of.

Ever-increasing demands make the use of modern simulation methods an indispensable tool for mastering the complexity required. The prediction of casting processes by numerical simulation has become indispensible. Computer simulations of the complex casting process often allow invisible problem areas to be located both qualitatively and quantitatively. Variations of parameters and the resulting effects can be investigated by computer, thus allowing purposeful optimization (Fig. 4). Software is available for linking various program packages (including CAD systems) and enabling direct communication between the foundryman and the designer [1], [2] (1981), [9], [12], [16], [59], [100], [101], [103], [104], [110], [111], [117], [133].

2.3. Casting in Nonpermanent Molds

2.3.1. Molding Materials, Binders, Additives, and Coatings

Nonpermanent molds and cores consist of the basic particulate material, a binder system, and additives. Additionally, mold coatings may be necessary.

The mold and the molding material have a decisive influence on the quality of the casting, for example, its dimensional accuracy, its surface quality, and its microstructure. The main demands made on the molding material are:

- Good workability
- Sufficient strength after shaping or during pouring and solidification
- Good disintegration characteristics after casting
- Highest possible accuracy of detail
- High refractoriness
- Sufficient gas permeability

– Negligeable undesirable interaction with the melt
– Uncomplicated reusability

The basic materials are granular substances of adequate refractoriness (washed, classified, and dried silica sand of the highest purity, zircon sand, chromite, olivine, corundum, magnesite, sillimanite, mullite, or chamotte). Binder systems may be inorganic or organic, natural or synthetic (Table 2). Additives to the molding materials improve their properties: flowability, compactability, bond improvement, prevention of sand expansion defects, breakdown properties. Common additives are sawdust, iron oxide, sugars, and glycol, among many others.

Some molding sand additives produce lustrous carbon, e.g., coal dust and hydrocarbons. These are vaporized at high temperatures and are simultaneously decomposed (cracked). The molding sand particles become coated with lustrous carbon and then are not easily wet by molten metal.

Figure 4. Design optimization by numerical simulation of casting processes

Table 2. Sand Binders

	Natural	Synthetic
Inorganic (in combination with water)	clays bentonites (mont-morillonite)	sodium silicate cement sulfite lye phosphate binders plaster
Organic (in combination with hardeners, catalysts and/or heat)	oil binders/ core oils sugar	condensation resins: aminoplasts (UF resins) phenoplasts (PF resins) furan resins reaction resins epoxy resins polyester resins polyurethane resins

Ready-to-use mold coatings are dispersions of finely ground minerals or refractory materials, and/or powdered coke in water or organic solvents, with a binder system and other additives to improve their application properties. They are applied to the surfaces of molds or cores, or if necessary to the surface of polystyrene patterns, the aims being to reduce metal penetration into the sand, to improve the casting surface finish, to facilitate separation of the casting from the molding sand, and to reduce fettling costs [2] (1981), [12], [15], [17] , [19–24], [25], [31], [32], [101], [128], [130], [131].

2.3.2. Molding Sand Preparation

Molding sand in a condition ready for use is produced by intensive mixing of the individual components or the use of pre-mixes with additives.

Usually, sand molds and, if possible, cores are made from used, reconstituted sand (old sand). The new sand supplied to the system should be used only for core making and for critical parts of the mold (facing sand). The amount of new sand should not be appreciably greater than the quantity lost in sand preparation. A mechanized foundry requires 5 – 12 t molding sand for every tonne of cast iron poured. The new sand also serves to maintain the sieve grading of the system sand.

Routine analytical control of the molding sand, including the testing of specimen cores, is at least as important as the quality control of the molten metal. Scrap rate due to mold defects can considerably exceed that due to metallur-

gical deficiencies; pinholes are often due to a combination of the two [20], [24], [26–29].

2.3.3. Clay Bonded Sand Molds

Natural sand (i.e., a naturally occurring sand – clay mixture) is now seldom used in foundries as a molding material. The more common synthetic sands are produced by mixing together the pure individual ingredients. The clay component is usually a bentonite (montmorillonite); natural sodium bentonites are preferred, or bentonites activated by ion exchange with sodium carbonate. Synthetic clay-bonded molding sand consists mainly of sand, bentonite, and a lustrous-carbon former (and, in the form of reclaimed sand, is usually already coated with lustrous carbon). It contains the amount of water necessary to give a bond (green sand). The water content is not decreased by any subsequent treatment of the mold. The quality of the molding sand is very dependent on the amount of fines present (arising from sand abrasion, active and dead-burnt bentonite, and carbonized lustrous-carbon former), and lastly on temperature, because the water content must be maintained at a low but precisely controlled level.

Green sand molds are produced by compaction of the prepared sand by, e.g., ramming, slinging, jolting, or squeezing. Compaction can also be achieved by gas pressure (explosion and air-impulse processes) or by an air stream.

Green sand molds that have been oven-baked or at least air-dried on the surface have much greater strength than undried molds and may be used for production of heavy castings, especially of steel, provided in this case no lustrous carbon is present.

Molds made using chamotte are used for heavy, thick-walled steel castings. Loam molds are now seldom used (template molding) [20], [30], [33], [37–43].

2.3.4. Chemically Bonded Sand Molds

Chemical binders can give well bonded molds with relative ease. The development of these products has made it possible to produce hard molds, often using simple methods. Good casting yields are obtained even without feeders (spheroidal graphite cast iron) and dimensional accuracy is also good. However, special care must be taken to protect the environment when organic binders are used [44].

Inorganic Binder Systems. Sodium silicate solution in the presence of an ester acts as a binder in a two-stage reaction (hydrolysis of the ester followed by gelling of the silicate at the lower pH). The bond strength and reaction velocity are dependent on the $SiO_2 : Na_2O$ ratio of the sodium silicate and the type and amount of ester used. The disadvantages are poor breakdown properties and difficult reuse of old sand. Better results are obtained with aluminum phosphate binders, which can be hardened with warm air or by adding strongly basic oxides, such as magnesium oxide powder. A typical application is mold manufacture with olivine sand, which is a self-hardener.

Other, less widely used sodium silicate systems use hardeners such as silicon–ferrosilicon powders (Nishiyama process, now obsolete because of the danger of hydrogen evolution), dicalcium silicate, or organic esters.

The importance of sodium silicate as a binder was first established by the hardening process involving gassing of the sand mixture with carbon dioxide. This process became of particular importance for core making on account of its rapid turn-around time (10 – 25 s), and it is environmentally extremely beneficial. Additives are used which reduce moisture pick-up on storage of the molds or cores, and also improve breakdown properties.

Cement is used as a sand binder in combination with hardening accelerators (e.g., molasses). This process is normally restricted to large, simply shaped molds. Dust problems render the process unsuitable for core making. In the fluidized sand process, the molding sand is prepared in a pumpable condition by the addition of surfactants and the incorporation of air bubbles [20], [45–48].

Heat Hardening Organic Binder Systems. In these systems molds and cores are produced by heat hardening of sands bonded with synthetic resins. They include the thermo-shock, hot box, warm box, and shell (Croning) processes, but not those processes that seek merely to improve hardening or to produce other effects. The

equipment used (pattern plates and core boxes) must be made of metal. The use of these processes is widespread; they give great dimensional accuracy and good breakdown properties.

Figure 5. Casting production by the shell process (Croning process) [11]
A) Metal pattern equipment heated to 250 °C; B) Dump box filled with coated sand; C) Pattern inverted to remove excess sand; D) Hardening of the shell mold; E) Stripping of the shell mold; F) Joining the two halves with adhesive; G) Pouring the mold on a bed of sand (or freestanding or in backing sand with mold vertical)

The *thermo-shock process* makes use of urea – furan – phenol resins with aqueous solutions of acid salts as catalysts. The sand mixture, which can include kaolin to improve the green sand strength, is hardened by heating in a mold at ca. 400 °C for a few minutes.

The *hot box process* uses similar liquid phenolic or furan resins, but with a latent acid catalyst, such as a solution of an ammonium salt. The hardening process, an exothermic reaction, takes place in 20 – 120 s in a core box preheated to 180 – 340 °C. The mixed sand has a limited bench life. There is no need for further hardening by oven baking.

The *warm box process* is an extension of the hot box process to lower working temperatures.

The *shell process* (Fig. 5) makes use of sand precoated with synthetic resin. This sand is dry, free flowing, and has a practically unlimited storage life. The resin is a condensation polymer not unlike that used in the hot box and warm box processes. The sand is coated with novolac resin using either the hot melt or cold solvent process. The pattern is preheated to ca. 250 °C and covered with the precoated sand that becomes hard where it is in contact with the hot surface, the depth of hardening (4 – 10 mm) being determined by the dwell time. The shell mold that is produced from the pattern plate in this way is bonded by an adhesive to a mold, usually another shell mold. Casting then takes place, either with the completed mold freestanding or embedded to withstand the metal pressure. When cores are made by the shell process, the free-flowing sand inside the cores may be emptied out (hollow cores) and re-used, or baked through (full cores) in an oven [12], [16], [34–36], [42], [45], [48].

Cold setting organic binders are systems with liquid hardeners and catalysts (no bake process), which are particularly suitable for making molds and larger cores, and systems with rapid-acting gas hardening, which are usually used for core making (cold box process).

No Bake Process. The mixed sands have a limited life, and distinction should be made between the time available for working with the sand (bench life) and the optimum time that should elapse before separating the hardened sand from the pattern or core box (strip time).

The cold setting oil process makes use of unsaturated vegetable oils (drying oils) in conjunction with organometallic accelerators (metallic dryers such as cobalt or lead naphthenate) and oxidizing agents such as potassium permanganate or sodium perborate. Hardening takes place at room temperature over a long period. Oven drying is used to complete the process. Alkyd resins may be used to supplement or replace the drying oils.

Furan resins are condensates between furfuryl alcohol and formaldehyde (urea modified). The hardening catalysts are acids such as phosphoric and sulfuric acids, or, particularly for re-

claimed sand systems, sulfonic acids. The addition of sulfuric acid increases setting speed.

Phenolic resins are hardened by sulfonic acids. These have only a limited storage life but are usually nitrogen-free and thermally more stable when hardened through. Other types of phenolic resins are formed from highly alkaline solutions of resoles by addition of an ester, which hydrolyzes in the alkaline medium and forms the acid necessary for gelling to take place. A combination of furan and phenolic resins is also possible.

The first urethane binder systems consisted of isocyanate and an alkyd resin, which are hardened by atmospheric oxygen in the presence of metal-ion catalysts. The more modern practice is to use a phenolic-based polyol, which reacts with a polymeric isocyanate in the presence of a basic catalyst [45], [49–51].

Gas Hardening Processes. In the cold box process, a mixed sand, usually including a multicomponent binder, is charged into a core box and then swept with a gaseous reagent or catalyst (with or without a carrier gas), thereby causing hardening of the sand, or speeding up a hardening process. The equipment must be sealed as the carrier gas (air) contains added or generated harmful gases or vapors. Heat may also accelerate the hardening process and can be provided either externally or by an exothermic reaction. Details of the common processes are given in Table 3 [20], [42], [45], [47], [49], [50], [52–54].

Physically Bonded Molding Materials. In the frozen mold process, moist sand without a binder is hardened by cooling, e.g., with liquid nitrogen.

In the magnetic mold process, a pattern made of foamed plastic (e.g., polystyrene) is surrounded by a ferromagnetic molding material (e.g., iron powder). During pouring and solidification of the metal, the molding material is held firmly in place by a strong applied magnetic field; the pattern is vaporized by the molten metal.

Another version of the full mold process with foamed plastic patterns uses dry sand. This is held in place merely by the gas pressure produced when the molten metal causes the pattern material to vaporize. The process may be improved by applying reduced pressure to the mold and by covering exposed sand surfaces as far as possible, e.g., with a plastic film.

Table 3. Common gas hardening (cold box) processes

	Gassing medium					
	Tertiary amine ∗		SO_2 (+N_2/CO_2)		Methyl	Acetal ∗∗
Resin component	phenolic resin polyisocyanate	furan resin	epoxy resin	acrylic resin	resole (highly alkaline)	polyphenol
Other component		peroxide	peroxide	peroxide (acid)	(ester)	acid
Polymer	polyurethane	furan resin	epoxy resin	acrylic resin	phenolic resin	phenolic resin

∗ Dimethylethylamine, dimethylisopropylamine, or triethylamine.
∗∗ For example, dimethoxymethane

In the vacuum process a film of thermoplastic material is placed over a special pattern containing many holes through which a vacuum is applied. The film is thereby stretched to fit the contours of the pattern exactly. A coating is applied, and, after inverting the pattern and placing it in a molding box, the molding box is filled with dry sand, covered with a second plastic film and a vacuum applied to the sand, enabling the pattern to be removed. A second molding box with its sand mold is then joined to the first in the usual way. Cores may be included. During the entire process up to the solidification of the metal, the vacuum must be maintained [20], [34], [45], [55, pp. 441 – 457], [56].

Precision Casting Processes. Molding shells are made by pouring a high-quality molding mixture onto pattern plates. In the Shaw process, a slurry of powdered refractories and ethyl silicate is used. This solidifies and is flamed off; the shells are then cemented together and heated to 800 – 1000 °C. In the Unicast process, the shells are dipped into a hardening bath instead of flaming off. Other variations are the Schott and Ceramcast processes [57].

Calcined gypsum is a suitable medium for both light and heavy metal casting. Combined water may be driven off by baking or calcining, giving modifications of the process such as the Capaco, Antioch, or foamed plaster processes [58].

Investment Casting. In this process, previously prepared one-piece wax patterns are coated or enrobed with the molding material, either one at a time or in clusters (Fig. 6). The patterns may be made of urea or of vaporizable foamed plastic. The running system (channels for the molten metal) is always part of the pattern. The process of covering the pattern is carried out by repeated application of coatings by dipping into a slurry or slurries consisting of refractory – binder systems, with a drying stage after each dip. The pattern material is then removed by melting, dissolving, or vaporizing, as appropriate; the mold is strongly heated and casting is carried out while the mold is still hot. Thin-walled molds require back-filling; thick shells do not [16], [19], [20], [42].

2.4. Casting in Permanent Molds

Permanent-mold casting is mainly used for low-melting nonferrous alloys (aluminum, zinc, magnesium, and copper alloys). In Germany, more than half of all nonferrous alloy castings are produced solely by pressure die casting. The main permanent-mold casting methods are gravity die casting, low- and counter-pressure die casting, and pressure die casting. The centrifugal casting process is mainly used for the production of spun iron pipes.

In *gravity die casting*, the melt enters the metallic permanent mold through the ingate simply by force of gravity. In *low-pressure die casting*, the melt is transferred from the furnace into the permanent mold above it through a pipe electromagnetically or by means of a slight overpressure of about 0.2 – 0.8 bar. In *counterpressure die casting*, not only the furnace but also the permanent mold are subjected to a pressure of up to 10 bar. Here too, mold-filling takes place due to a slightly higher pressure build-up in the furnace than in the mold. These two pressure-assisted methods allow very smooth, homogeneous filling of the mold. The permanent mold is usually treated with a ceramic coating to protect it from the melt and to regulate heat loss. This layer must be replaced at regular intervals. Maintaining the heat balance usually also requires the thermal energy brought into the die by the melt to be removed by cooling. Proper die design and well-planned location of the cooling channels allow

for controlled solidification in the direction of the gatings or the filling pipe and thus ensure a sound casting. In order reproduce undercuts and as-cast holes, the dies can be divided into several sections and be furnished with core pullers. It is also possible to place sand cores in the mold in order to form hollow spaces within the casting.

In *pressure die casting*, the molten metal is filled into a casting chamber and then pressed into the metallic permanent mold at high pressure. Because the filling time is very brief (20 – 500 ms, depending on wall thickness and size of the casting) and due to the pressure which the molten metal is subjected to even in thin cross sections, it is possible to attain a wall thickness of under 1mm and highly exact reproduction of the desired contours. Today, except in rare cases, hot and cold chamber die-casting machines are used. Hot-chamber machines are well suited to low-melting metals. Heavy metals such as zinc, lead, and tin alloys, as well as magnesium alloys, are cast by this method. The casting chamber sits in a bath of molten metal and takes on its temperature (this explains the term ″hot chamber″). Cold-chamber machines are suitable for higher-melting metals such as aluminum, magnesium, and copper alloys. In the cold-chamber machine, the metal is kept hot in a separate furnace next to the machine and then filled into the pressure chamber by means of a ladle or a dosing system. (The term cold chamber refers to the fact that it is ″cold″ compared to the melt in the furnace). The two halves of the permanent mold have water or oil channels to attain the optimal working temperature by regulating the heat balance in the mold. Properly dimensioned and located channels can influence localized heat distribution, a factor of great importance, especially for complex castings.

To achieve higher quality, mainly for aluminum components, the thixocasting and the squeeze casting processes have been developed. In thixocasting semi-solid slugs with a melt content of about 50 % are processed by the pressure die casting method. The behavior of the semi-solid material during mold filling differs from that of a liquid melt. This results in a better quality casting and makes it possible to use high-strength alloys which normally are not suitable for the pressure die casting method. In squeeze casting, the melt solidifies under a very high pressure of 1000 bar and more. Slow filling of the mold and high melt quality are important. Castings made by this method are of very high quality [4], [34], [59–61], [63–65], [111], [116], [118], [121–123].

3. Melting, Pouring, and Solidification of Metals

3.1. Melting, Holding, and Pouring

Melting shops have various methods of producing and casting molten metal. On average, their costs amount to about one-third of total foundry costs. Therefore, the melting shop must be optimally coordinated with the rest of the plant. Flexibility in the production of the melt and in carrying out necessary metallurgical procedures, as well as the ability to provide molten metal over longer periods of time, require well-adapted production units (furnaces specifically adapted to the alloys, the lot sizes, the cycle time, etc.). Another essential aspect is that the quality of the cast part depends decisively on the melting technique. The most widely used industrial furnaces are currently the cupola furnaces, used by iron foundries to produce molten iron, and induction and resistance furnaces, which are used especially for nonferrous metals but also for cast-iron materials.

The cupola furnace is based on the principle of the vertical shaft furnace. The charge, which is loaded in layers, undergoes continuous melting in the cupola furnace. The charge mixture consists mainly of the fuel (usually coke, but oil or natural gas firing is also possible), the metal charge (pig iron, scrap and recycled iron) and (slag-forming) additives. The coke provides the energy, that is, the energy required for the melting process is produced within the cupola furnace. As a result of the continuous melting process, the metal charge gradually slides into the furnace shaft where it is heated by the rising gases. In the adjacent melting zone, the iron liquefies and, after superheating, collects on the floor of the furnace before leaving the furnace through the tapping hole. The intense contact between the molten iron and the coke causes carbon pick-up in the liquid iron.

In induction melting, heat is produced directly within the metal charge by the magnetic field of a primary coil. Industry uses

mainly medium-frequency and, occasionally, low-frequency crucible furnaces. Both types of furnace are very economical compared to other melting units. The metal charge is placed directly in the crucible and it is possible to begin the melting process even while the metal is still cold. All common cast iron materials can be melted in the induction furnace. The intensive movement caused in the molten material by the eddy current leads to a high melt-down rate for the metal charge and the alloying metals, and produces high regularity and homogeneity in melt composition.

In the resistance crucible furnace, heat is produced in electric heating elements and transferred to the metal by radiation, convection, or conduction. The advantages of the resistance furnace are that it can be used universally and requires minimal maintenance. Due to its low efficiency, it is now widely being replaced by small medium-frequency induction furnaces. It is, however, still in use as a holding furnace for lightweight metals in pressure casting processes [6], [7], [14], [66–69], [101], [102], [119–121].

3.2. Solidification Morphology

The solidification process of the metallic materials plays an important role both in determining the casting procedure and in the properties of the casting. During solidification, metals form crystals. The actual casting does not consist of a single ideal crystal but of many crystalline grains. The crystals form as the melt solidifies, developing in random fashion in various areas of the melt and increasing in size until they meet and limit each other's growth. The size, growth, and position of the crystals which make up the casting material are referred to as the microstructure of the casting. In some alloys, such as cast iron, additional microstructural transformations occur on cooling to room temperature.

In practice, inoculations and grain-refinement treatments are carried out to influence microstructure formation. These change the nucleation conditions in the melt or the growth conditions of individual crystals. Regulating heat transfer from the solidifying metal to the mold material can also modify the microstructure of the casting.

Another important property of metals that has a major influence on the casting process is the volume of contraction during cooling of the melt, solidification, and final cooling of the solidified casting (Fig. 7). The feeding, which is an essential aspect of the casting process, is conceived to balance out the differences in volume which arise during cooling and solidification of the melt. The differences in volume depend on the alloys involved. Gray cast iron and nodular cast iron increase in volume during solidification. Whereas only liquid and solidification shrinkage are of importance for casting and feeding technology, pattern and mold construction are decisively influenced by volume shrinkage in the solid state. The extent of this shrinkage also depends on the alloy. The dimensions of pattern and mold must be increased such that after shrinkage, the required size is attained at room temperature [26], [113–115].

4. Aftertreatment of Castings

4.1. Cleaning of Castings (Fettling)

In nonpermanent-mold casting, separation of the casting from the mold is carried out by breaking down the bond of the molding material with vibrating grates, tumbling mills, heavy hammers, or water jets. The surfaces are then cleaned and descaled by shot or sand blastin, or tumbling, and ground smooth. In permanent-mold casting, the surface is normally not treated.

The gating and running systems are removed by knocking off, abrasive cutting, or flame cutting. The removal of surface unevenness and defects, especially flash and fins, is carried out by grinding with abrasive wheels; this is often expensive, as these operations even today are very labor intensive [55, pp. 458 – 461], [70–89], [129].

4.2. Heat Treatment

Heat treatment is carried out, if required, to modify the metallic structure of the whole casting (e.g., annealing, tempering, hardening, hardening plus tempering, age hardening) or the surface (e.g., surface hardening or nitriding by gas or salt bath treatment). Stress-relief annealing removes shrinkage stresses (cooling stresses) without altering the structure of the metal [90–92], [112].

5. Control of the Casting Process

5.1. Quality Assurance

The manufacture of a casting is complete only when it meets the set requirements. Quality assurance is vital at all stages, from raw materials to casting design. Quality assurance prevents casting defects, or, failing this, it finds and rejects defective castings. Defective castings may sometimes be salvaged, e.g., by welding or heat treatment. The statistical analysis of production data and test results forms the foundation of every type of production control procedure. The test methods themselves and the associated costs are determined by the particular quality requirements (Table 4). Corrosion protection of the castings is another aspect of quality assurance [16], [93].

Table 4. Quality control of castings

Properties	Tests
Test castings	wedge test wall thickness test fracture surface, microstructure, hardness
Composition	chemical analysis
Surface	visual inspection (roughness, defects) crack tests – penetrant materials – magnetic powder
Measurements	dimensions, weights, distortion
Density,	weight
inclusions	tests using sound waves radiographic methods
Hardness	file test (machineability) point load tests (Rockwell, Brinell, etc.)
Structure	micrography physical methods
Mechanical properties	test pieces taken from the casting or
(static and dynamic)	specially cast nondestructive tests

5.2. Protection of the Workplace and the Environment

While the cast product, like any other metal product, has always been completely recyclable as scrap, the production process does leave

residues that are currently not reusable. In terms of environmental protection, foundries do need to pay specific attention particularly to dust, noise, sludge, exhaust, effluent and solid wastes produced especially by casting and melting, by the mold (treatment, regeneration, preparation, release agents, and coatings) and in the cleaning department. Used sand, which makes up about 75 % of the waste produced by foundries, has become an important cost factor, primarily due to rising disposal-site costs. Modern developments in the foundry business include waste reduction by optimization of the production process, recycling and reprocessing of materials, and, as a last resort, treatment of the waste materials before disposal to render them innoccuous [94–96], [97–99], [131], [132], [134–140].

1. Introduction

Fructose, also known as fruit sugar, is a ketohexose ($C_6H_{12}O_6$) monosaccharide reducing sugar found widely in the plant kingdom. Fructose is the sweetest naturally occurring sugar. In its free monosaccharide form fructose is present in notable quantities only in honey and a few fruits (dates, figs, apples, grapes, and most berries). As a constituent of the disaccharide sucrose, which consists of D-fructose and D-glucose residues in glycosidic union, fructose is an important part of everyday sugar usage [1]. Oligo- and polysaccharides of D-fructose (fructans) are present in many plants.

The common name “levulose” was adopted for D-fructose in 1890 after the observation that D-fructose rotates polarized light to the left in aqueous solution [2].

Production of fructose by alkaline isomerization of glucose was reported in 1895 by Lobry de Bruyn and van Ekenstein, but various attempts at commercializing such a process never materialized. Today fructose is produced on a large scale from the raw materials starch, sucrose, and inulin. The industrial-scale production of fructose was made possible by significant advances in enzymatic processes and the development of chromatographic separation technologies in the 1960s and 1970s. Fructose contributes many useful physical and functional attributes to food and beverage applications, and thus fructose can be used as a sweetener in any food.

2. Structure, Physical and Chemical Properties

2.1. Structure

D-Fructose [57-48-7] is a monosaccharide with the chemical composition $C_6H_{12}O_6$, M_r 180.159 g/mol. According to IUPAC nomenclature fructose is (–)-D-arabino-hex-2-ulopyranose [3]. Fructose is a 2-ketohexose, that is, a six-carbon pentahydroxyketone with a keto group at C-2. Due to the keto functionality fructose acts as a reducing sugar.

In the solid state and in solution fructose exists in a cyclic hemiacetal form, the preferred five-membered ring known as furanose. Cyclization results in the generation of a new asymmetric center, the anomeric carbon C-2, thereby giving rise to diastereoisomeric hemiacetals which are called anomers and labeled α and β.

The structure of fructose contains three asymmetric centers, thus eight stereoisomers exist. They can be grouped into four pairs of enatiomers, and classified as D- and L-sugars. The isomers of fructose are the ketohexoses sorbose [3615-56-3] (D), tagatose [87-81-0] (D), and psicose [551-68-8] (D).

Anomeric configurations (α and β forms) and different ring sizes (pyranose and furanose) interconvert in solution through a ring-opening reaction called mutarotation. Fructose dissolved in water consists of a mixture of five tautomers (Fig. 1).

Figure 1. Distribution of frutose tautomers in water at room temperature.

At room temperature, the composition of a 10 wt % solution is 0.5 % α-fructopyranose, 71.4 % β-fructopyranose, 5.5 % α-fructofuranose, and 22.3 % β-fructofuranose, the acyclic keto form being on the order of 0.5 %. The β-pyranose: β-furanose ratio increases with increasing temperature (0 to 60 °C) [4]. As an explanation for the large fraction of β-fructopyranose proportion in D-fructose, the presence of an intramolecular hydrogen bond between the primary 1-OH and the 3-OH groups is invoked [5].

β-D-Fructopyranose is the normal crystalline form of fructose and it is the only tautomer which has been isolated. Other tautomeric forms are isolated as derivatives. β-Fructofuranose is most prevalent for fructose bound in naturally occurring compounds like sucrose [57-50-1], raffinose [512-69-6], and inulin [9005-80-5].

Different conformations for pyranoid sugars are described as chair (C), boat (B), half chair (H), and skew (S). The chair form of fructose follows a similar pattern as that of glucose with a few exceptions. Since fructose has a keto functional group, ring closure occurs at C-2. In the case of fructose a five-membered ring is formed. The OH group on C-5 is converted to an ether linkage to close the ring with C-2. The preferred conformation for β-D-fructopyranose is the $^2C_5$ chair conformation. Envelope (E) and twist (T) arrangements are the principal conformation of the furanose ring. The exact conformation of an individual furanose is not known.

The rare ketohexose L-fructose [7776-48-9], which does not exist in nature, can be synthesized by chemical procedures or by microbiological methods such as enzymatic preparation from L-mannose or bacterial oxidation of L-mannitol to L-fructose. All methods are very elaborate and not suitable for mass production of this sugar [6].

2.2. Physical Properties

The most comprehensive tabulation of physical properties of D-fructose can be found in *Sugar Technologists Manual* [7].

Fructose crystallizes as colorless crystals with a white appearance. The crystals are anhydrous. The density of the solid crystalline phase is 1.60 g/cm^3. The specific enthalpy of combustion is 15 600 kJ/kg. The melting temperature of D-fructose is 378.15 K, and the molar enthalpy of melting 33.0 kJ/mol [8]. Due to its relatively low enthalpy of solution of –37.69 kJ/kg (–6.79 kJ/mol) no cooling effect in the mouth is caused by fructose.

The fundamental knowledge of the macroscopic and molecular behavior of concentrated aqueous carbohydrate solutions is also the basis for the understanding of the process of crystallization [9]. The nucleation, growth kinetics, and the extent of oversaturation are influenced by the liquid film surrounding the crystals [10]. Beside the well-known and preferred anhydrous D-fructose other crystalline phases such as D-fructose hemihydrate and D-fructose dihydrate were determined [11].

Solvents for fructose are water, pyridine, quinoline and a series of polar aprotic solvents. The solubility of fructose in alcohols is limited [31]. Fructose has a solubility of 4 g per gram H_2O at 25 °C, the highest solubility of most, if not all, sugars and sugar alcohols. The dry substance content w_{DS} of a saturated fructose solution is 78.9 % at 20 °C and 88.1 % at 55 °C [7]. It is for this reason that fructose is so difficult to crystallize from aqueous solution [12].

Because of the high solubility of fructose in water industrial crystallization from aqueous solution has to cope with high viscosities. In comparison with a dynamic viscosity η = 96.5 mPa·s of a saturated sucrose solution at 50 °C a saturated fructose solution at this temperature shows a viscosity of η = 1630 mPa·s. Successful crystallization can only be achieved by

defined process control. Such a control may be improved by modeling based not only on viscosity data but also on diffusion coefficients of water and the different tautomers of this sugar.

The water activity and solubility of fructose, other sugars, and polyols are listed in Table 1. Other properties are summarized in Table 2. [7], [13]. Table 3 lists the dynamic viscosity and density of aqueous fructose solutions[12].

Table 1. Comparison of water activity (a_W– value) of saturated solution and solubility at 25 °C for selected crystalline sugars and polyols[12]

Compound	Water activity at 25 °C	Solubility at 25 °C, g/g water
Mannitol	0.977	0.22
Maltose	0.952	0.85
Lactose (monohydrate)	0.931	0.23
Dextrose (monohydrate)	0.891	1.04
Sucrose	0.844	2.07
Sorbitol (gamma)	0.725	2.7
Fructose	0.634	4

Table 2. Physical properties of D-fructose

Property	Unit	Value	Ref. [7], page
Molar mass (anhydride)	g/mol	180.159	117
Density (β-anhydride)	g/cm^3	1.60 (20 °C)	117
Melting point (β-anhydride)	°C	103–105	117
Enthalpy of solution	kJ/mol (kJ/kg)	–6.79 (–37.69)	117
Specific rotation $[\alpha]_D^{20}$	°	–133 to –92	117
Dissociation coefficient pK_1		11.90 (20 °C)	120
Osmotic pressure Π (100 g/L H_2O)	kPa	1275	172
Density of pure fructose solution (w_{DS} = 70 %)	kg/m^3	1344.6	171, 173, 187
Refractive index n_D^{20} (w_{DS} = 70 %)		1.461654	166, 177, 188
Dynamic viscosity η (w_{DS} = 70 %)	mPa·s	178.00	175/176
Physiological calorific value	kJ/kg	15 600	117
Freezing point depression (t_f (w_{DS} = 20 %)	K	2.64	183
a_W– value (saturated solution)		0.63	183

Table 3. Dynamic viscosity and density of pure aqueous fructose solutions in kg/m3 at 20 °C [7]

w_{DS}	20 %	30 %	40 %	50 %	60 %	70 %
η, mPa·s	1.82	2.84	5.01	10.70	32.3	178.00
ϱ, kg/m^3	1081.6	1127.7	1177.1	1229.7	1285.6	1344.6

For the dynamic viscosity η, density ϱ, and refractive index n_D, algorithms for a broad range of concentrations and temperatures are given in [7], [14], [15]. The dependence of the viscosity on concentration and temperature has been investigated for a better understanding of crystallization process [9].

Water vapor sorption is the most relevant property concerning the storage characteristics. The predominant interaction of crystalline sugars with water vapor is by surface adsorption. At critical relative humidity (RH_0) they may deliquesce. For fructose RH_0 is 64 % at 25 °C [16].

Fructose is the sweetest natural sugar. The sweetness of crystalline fructose is 1.8 times that of sucrose, whereas the sweetness of fructose solutions is not as high. In this respect, fructose would be the ideal nutritive sweetener because it would give the same texture and sweetness to food as sucrose but with a lower energy content. However, when fructose is in solution the relative sweetness varies with temperature, pH, and concentration [17]. The relative sweetness of fructose

increases with decreasing temperature and vice versa. This phenomenon could be explained by greater formation of furanose forms at higher temperatures.The sweetness of fructose also increases with increasing acidity [18].

2.3. Chemical Properties

Fructose exhibits the same reactions as other carbohydrates to form esters, ethers, and acetals [19], [20]. Typical carbonyl reactions with nucleophiles such as amino acids, peptides, or other amino-group donating compounds could be realized. The mild acid-catalyzed alkylation of fructose with alcohol results in fructose glycosides [21].

Under alkaline conditions fructose undergoes *isomerization* via the 1,2-enediol to the aldose glucose, which can epimerize to mannose. The total rearrangement is known as the Lobry de Bruyn – van Ekenstein reaction [22]. Fructose is converted to the stable aldohexoses glucose [50-99-7] and mannose [345-28-4] and a small amount of psicose [551-68-8]. Isomerization under alkaline conditions and elevated temperatures is followed by fragmentation, and the resulting products are glyceraldehydes, lactic acid, methyl glyoxal, etc.

Reduction of D-fructose by the enzyme ketose reductase can lead to either D-sorbitol [50-70-4] or D-mannitol [69-65-8] [19]. Commercial mannitol production is based on catalytic hydrogenation of the keto group of fructose with the help of heterogeneous metal catalysts such as Ni or Cu. Depending on the selectivity of the metal catalyst 40–70 % of mannitol is obtained from a 100 % fructose solution. Mannitol can be purified by crystallization or chromatographic separation, since sorbitol is formed as well. Mannitol is used in chewing gums, for example, and in pharmaceutical preparations [25].

Heterogeneous catalytic *oxidation* of fructose is performed with air or molecular oxygen in the presence of supported noble metal catalysts [25]. Well-known catalytic systems are Pt/C and Pd/C. Apparently, in ketoses like fructose the primary hydroxyl group on C-1 is activated by the adjacent carbonyl group, and this OH group is attacked preferentially to the other primary hydroxyl group at C-6. Catalytic oxidation of D-fructose leads to two major products: 2-keto-D-gluconic acid [328-50-7] (60 %) and D-*threo*-hexo-2,5-diulose (“5-ketofructose”) [26].

Heating fructose above the boiling point of concentrated solution or the sintering range of the crystalline substance leads to *dehydration* with anhydride formation or caramelization [27]. The formation of condensation products such as difructose dianhydride by elimination of water is dependent on the concentration of fructose, pH, and temperature.

Thermal decomposition of fructose in the presence of amino acids leads to Maillard products, color- and flavor-giving components. This reaction is responsible for the nonenzymatic browning of foodstuffs.

The acid-catalyzed conversion of concentrated aqueous fructose to 5-hydroxymethylfurfural (HMF) [67-47-0] has been known for a long time [28]. The ketose fructose is much more suitable to opening of the ring followed by rearrangement to form the acyclic 1,2-enediol intermediate than glucose. Subsequent dehydration of the enediol leads to 5-hydroxymethylfurfural with removal of three molecules of water. Thus fructose is a good starting material for production of HMF. The HMF can be rehydrated in the presence of two equivalents of water to form levulinic and formic acids [29].

Figure 2. Formation of HMF.

Due to its wide range of diverse industrial applications, many suggestions have been made to utilize this dehydration reaction in a commercially practical manner for the manufacture of HMF. Based on renewable resources, HMF is suggested to be a very interesting and versatile intermediate product [30]. However, despite the fact that the technology of HMF production has been elaborated on a pilot-plant scale, it is not produced on industrial scale.

Monosaccharides like fructose are starting materials in the *enantiospecific synthesis* of natural products. The advantage of using monosaccharides like fructose as a chiral pool are commercial availability, low cost, valuable carbon source, enantiopure materials, and several defined chiral centers.

Rare sugars such as *D-psicose* could be made from D-fructose by using D-tagatose 3-epimerase from *Pseudomonas cichorii* ST-24. After epimerization the substrate D-fructose was removed by treatment with baker’s yeast [32].

[Top of Page]

3. Raw Materials

Fructose occurs widely in the plant kingdom in its free form or in free sucrose, which consists of D-fructose and D-glucose residues in glycosidic union. Polysaccharides of D-fructose (fructans) are common in many plants. The largest amount of fructose is found in honey (40 g/100 g), apples (6–8 g/100 g), pears (5–9 g/100g), prunes (15 g/100g) and their juices [P 993].

Under the aspect of economy the primary raw materials used worldwide for the production of fructose are starch, sucrose, and inulin.

Starch is a storage carbohydrate in many plants such as corn, barley, wheat, rice, potato, tapioca, and other starch-bearing grains and roots. Starch is a polysaccharide consisting only of glucose units. A precondition for making fructose from sources which consist only of glucose is easy conversion to fructose. The most important plant for fructose production from starch is corn.

Sucrose, a disaccharide consisting of fructose and glucose, is produced from sugar beet or sugar cane on a very large scale (140×10^6 t/a) worldwide. Sucrose is almost an ideal raw material because of its extremely good availability, high purity, and the high content of fructose (equimolar mixture with glucose) after hydrolysis.

Materials that are naturally rich in fructose include the storage carbohydrates fructans such as inulin or levan. Fructans are made up of D-fructose residues linked to a terminal sucrose residue. Planting, harvesting, and scale of production have to be economically efficient [33], [34]. Materials such as roots of chicory, tubers of Jerusalem artichoke, tubers of dahlia, and hearts of globe artichoke are rich in fructan [24], [35].

Levan consists mainly of β(2,6) linked fructosyl-fructose bonds and is today irrelevant as raw material for fructose production, whereas fructose production based on the raw material inulin is carried out on a large scale. The primary sources for industrial-scale inulin and inulin/fructose production are artichokes and chicory. The chicory root, for example, has an inulin content of 15–20 %. Inulin is a polydisperse mixture of molecules with the basic chemical structure GF_n where G is the glucosyl moiety, F is the fructose moiety and *n* is the number of fructose moieties linked by β(2,1) linkages. The degree of polymerisation (DP) of inulin typically ranges from 3 to 60.

Virtually, all of the inulin produced in the EU is derived from the chicory root. The European inulin industry is relatively new, having only been established in 1984 [36]. In addition to the industrial application of inulin, it is used as a source of fructose and oligofructose. Oligofructose, which is partially hydrolyzed inulin, consists of between 2 and 20 fructose units and provides nutritional and functional advantages.

[Top of Page]

4. Production

4.1. General Aspects

Production of fructose by alkaline isomerization of glucose was reported in 1895 by Lobry de Bruyn and van Ekenstein, but various attempts at commercializing such a process never materialized due to low fructose yield and formation of color, off-flavor, and other byproducts [20].

The industrial-scale production of fructose syrup was made possible by significant advances in industrial isomerization and the development of chromatographic separation technologies in the 1960s and 1970s. The most sophisticated technological step in the production of fructose from the raw material sucrose or starch is chromatographic separation of the fructose/glucose syrup. Separation is achieved on a strongly acidic cation-exchange resin in the calcium form. In the past batch systems were used, but more recntly the simulated moving bed (SMB) process became more and more mature, and today it is the state of the art. All newly built plants will use SMB technology for the separation of fructose and glucose. The main advantages are the lower water consumption, lower steam consumption, and high recovery rate. Suppliers of classical SMB systems use resin beds with different depths and different types of resin compartments. One supplier has installed the compartments on a carousel in order to replace the on/off valves with a rotary valve The carousel rotating under the distribution ports moves up to 20 large columns [37]. In a sequential simulated moving bed system (SSMB), the streams do not flow continuously. Each step is divided into two periods: one with production flows and one with just circulating stream flowing in a loop. The division of each step allows much better defined fraction cutpoints. Depending on the capacity in the sugar industry for sugar separation, a bed size of several 100 m^3 is required [38], [39].

For reliable modeling and design of a large-scale SMB operation it is crucial to understand the properties of the adsorbent, adsorption equilibria (partition coefficients), and mass transfer rates. The resins have a volume-weighted median pore size of 1 nm, roughly equal to the diameter of the hydrated sugar molecules [40].

Another technological improvement that made the production of fructose syrups more effective was the use of monodisperse ion-exchange resins for the chromatographic separation. The use of these resins leads to higher recovery, lower dilution, and improved overall operating efficiency.

4.2. Production from Starch

To produce fructose syrup from the glucose polymer starch, enzymatic processes (see also ⟶ Enzymes – Immunoassays) had to be first developed for liquefying starch, converting liquefied starch to glucose, isomerizing glucose to fructose, and separating fructose from the solution. Fructose, however, is not a starch hydrolysis product per se [20]. The starch is converted to glucose by using enzymatic processes with α-amylase (E.C. 3.2.1.1) [9000-90-2] and glucoamylase (EC 3.2.1.3) [9032-08-0] and the glucose syrup is epimerized to a mixture of fructose and glucose by using glucose isomerase.

Glucose isomerase (D-xylose isomerase, E.C. 5.3.1.5) [9055-00-9] catalyzes the isomerization of D-glucose to D-fructose. The enzyme is actually a xylose isomerase, but also isomerizes D-xylose to D-xylulose, as well as D-ribose to D-ribulose. The isomerase is specific for the α-anomeric form of the substrate. The kinetics of the glucose isomerase are dependent on various metal ions and pH values [41]. Glucose isomerase is activated by magnesium, and calcium acts as enzyme inhibitor. Isomerization of glucose to fructose is a thermodynamically controlled reaction. The equilibrium constant of this reaction is approximately unity at 60 °C.

In the 1950s, several enzymes were discovered that had the ability to convert three-, four-, and five-carbon aldoses to the corresponding ketoses. An industrial process for isomerization of glucose to fructose was developed and commercialized in 1966. Since 1968, a 42 % fructose syrup, high-fructose corn syrup (HFCS) has been manufactured by the enzymatic route. The soft drink industry began to substitute high-fructose syrups for sucrose from the late 1970s onwards. By chromatographic separation the fructose purity is increased to at least 90 %, followed by crystallization.

4.3. Production from Sucrose

The first commercial process for the production of crystalline fructose was based on sucrose as raw material. (Fig. 3). Sucrose is hydrolyzed and subsequently separated into glucose and fructose by chromatography.

Figure 3. Production of fructose.

The hydrolysis of the disaccharide sucrose to its free component sugars fructose and glucose can be affected by different kind of technologies like enzymatic reaction or homogeneous or heterogeneous acid-catalyzed reaction.

Hydrolysis can be performed by a highly specific enzymatic reaction using an invertase from *Saccharomyces cerevisea*, namely, β-D-fructofuranosidase (E.C. 3.2.1.26) [9001-57-4]. Drawbacks of this technology are the costs of enzyme and the batch process. Until now immobilized invertase has not been used in an industrial production process.

Homogeneously catalyzed hydrolysis by acids is accomplished by free mineral acids permitted by food regulations, such as hydrochloric acid or sulfuric acid. The degree of inversion is precisely adjustable by means of a neutralization step at the end of the reaction with NaOH or KOH. High ash content is caused by this method. The reaction conditions with high temperatures and low pH are quite harsh and lead to undesirable byproducts.

State of the art for sucrose hydrolysis is the use of immobilized acids such as strongly acidic cation exchangers in protonated (H^+) form in a fixed-bed column. The resins have legal approval for food production. In a continuous bulk production sucrose solutions with 50-60 wt % can be completely hydrolyzed at an inversion temperature of 30-45 °C, and a practically ash-free product with avoidance of undesirable materials is obtained.

The resulting hydrolyzate is the feed for the chromatographic separation. The batch process is being replaced by semicontinuous or continuous SMB technology. The two fractions of this separation have a minimum purity of 95 %. The following crystallisation step is described in Section Crystalline Fructose.

4.4. Production from Inulin

Chicory processing has evolved from laboratory to full industrial scale since the mid-1990s. In the EU this route has become very important for the production of fructose but also for inulin and oligofructose [24].

For the production of fructose from inulin a hydrolysis step is needed. This can be done by acid catalysts or with the help of enzymes. Acids such as sulfuric, hydrochloric, phosphoric, citric, oxalic, and tartaric acids perform the hydrolysis reaction effectively but they suffer from the drawbacks of promoting the decomposition of fructose and of contaminating the product. To overcome these drawbacks, academic projects were performed with acidic zeolites as catalysts for hydrolysis of inulin to fructose. This reaction is relatively fast and does not decompose fructose. Presently this route of production is only of academic interest [33].

Given the drawbacks of acid hydrolysis the use of enzymes is the preferred strategy. A mixture of the enzymes exo-inulinase (E.C. 3.2.1.80) and endo-inulinase (E.C. 3.2.1.7) from fungi (e.g., *Aspergillus niger*, Fructozyme from Novozymes) hydrolyzes inulin to fructose in a single-step reaction [35]. In contrast, conventional fructose production from starch needs at least three enzymatic steps and yields only 45 % of fructose [42]. Partial hydrolysis yields oligofructose, which consists of between 2 and 20 fructose units.

The hydrolysis of inulin can be carried out batchwise in large tanks with holding times of between 12 and 24 h. A solution of 10–20 wt % dry substance is preferred. The fructose content of the syrup produced varies with the source of inulin and the harvesting time of the plant, but is usually between 85 and 95 %, the rest being 3–13 % glucose and 1–2 % oligosaccharides. A temperature of 60 °C is recommended. Activity is optimal in the interval between 57 and 63 °C. Above 63 °C the stability of the enzyme is markedly reduced. At lower temperatures the rate of hydrolysis is reduced and the risk of microbial infection is increased. The enzymatic hydrolysis is carried out in neutral or slightly acidic medium. After hydrolysis the syrup is demineralized, decolorized, and further concentrated. The resulting fructose syrup has a high fructose content of 85 % or more. The advantage of the enzymatic route is the avoidance of aftertaste and degradation products.

If higher purities are required a chromatographic separation process is possible. A process without additional fractionation or refining giving purities of at least 93.5 wt % is described. The fructose content is strongly dependent on the degree of polymerization of the raw material [35].

4.5. Crystalline Fructose

The crystallization of fructose is the most difficult part of the whole process due to the physicochemical properties and a number of unfavorable reactions that can take place. The crystallization process itself can be batch or continuous. Independent of the raw material a fructose syrup with at least 90 % fructose in the total solids content is needed as starting point for successful crystallization of pure fructose. A number of different aqueous and solvent processes have been proposed for the crystallization of fructose. Due to the very costly removal and recovery of the solvent from the product the most successful crystallization processes in use today are based on the crystallization of fructose from aqueous solution [20].

Various combinations of concentration under atmospheric or reduced-pressure conditions and seeding to initiate crystallization followed by a cooling step to allow for crystal growth are utilized. One process involves cooling an aqueous solution with a solids content of 85–95 % from 65 to 25 °C at a rate of < 1 °C/h. Batch and continuous crystallization processes have been devised that incorporate preprogrammed concentrating, cooling, warming, and recooling cycles. To produce a high purity product that will remain free-flowing and granular during storage, the crystals must be thoroughly freed of mother liquor. This is done in centrifuges, generally of the basket screen type, which include a washing zone or cycle to rinse the crystals free of any remaining mother liquor. The crystals are then exposed to a further drying step to remove surface moisture to prevent lumping and give a good storage quality [12].

Impurities such as glucose and difructose dianhydrides have a negative influence on the crystallization of anhydrous fructose from aqueous solution. Glucose is the major impurity likely to be present in fructose syrup from starch or sucrose, while several difructose dianhydrides are formed in situ under crystallization conditions. Both sets of impurities were found to inhibit crystal growth, but the mechanisms responsible in each case are different [43]. The presence of glucose increases the solubility of fructose in water and thus lowers the supersaturation of the solution. This is probably the main effect responsible for the decrease of crystal growth. The decrease of crystal growth by difructose dianhydrides is probably caused by the incorporation of these impurities into or adsorption on the crystal surface, which would accept fructose molecules in the orientation that existed in the difructose dianhydride [43].

4.6. Further Developments

Research and development activities for improvement in fructose production are focused on raw materials, enzymatic conversion, and chromatographic separation.

The combination of reaction catalyzed by enzymes and a chromatographic separation in a single unit operation is proposed for the simultaneous inversion of sucrose [44] or the enzymatic isomerization of glucose to fructose and the separation of glucose and fructose. In the case of the isomerization the idea is to shift the reversible reaction towards the favorable product fructose by combining an immobilized enzyme reaction and adsorption. The bioreactor was applied to production of higher fructose syrup. This technology is not mature and work has been done on lab scale or modeling working groups [23]. One of the aims of the last few decades has been to directly obtain fructose purity of 90 % by genetically modified enzymes in the isomerization step. Another aim is to crystallize and separate fructose and glucose directly from lower purity high-fructose syrups [8].

The production of enriched fructose syrups and ethanol from a medium with high sucrose concentration was studied in a batch process using a mutant of *Saccharomyces cerevisiae* [45].

The production of inulin with a high degree of polymerization from sucrose by microorganisms could be an alternative to native inulin [46].

[Top of Page]

5. Uses

Fructose was positioned early as a nutritionally advantageous sweetener because of the special metabolic properties. Therefore, many of the products first sold that contained fructose were dietetic products such as meal replacers and diabetic foods. These included various powdered diet beverages, nutritional candy bars and other specialty food items [12]. Fructose contributes many useful physical and functional attributes to foods and beverages, and thus fructose can be used as a sweetener in any food.

As a result of the exceptional sweetening power fructose is used primarily for added sweetness in low-calorie foods. Its tendency to confer “body” on a product is a major advantage over intense sweeteners. The synergetic effects with other sweeteners such sucrose allow a reduction in amount of sweetener and calories without a reduction in perceived sweetness. Its ability to enhance flavors is remarkable, especially for fruit flavors. Consequently, reduced levels of sweeteners and flavors could lead to saving of costs. High solubility at low temperature and large freezing-point depression of fructose are particularly interesting for ice cream and frozen-dessert manufacturers, since these properties influence product taste and texture. Fructose is superior to all nutritive sweeteners and humectants in controlling the water in frozen systems.

For baked goods the benefits of fructose can be seen in its influence on moisture management which leads to extended shelf life, color development due to intense browning, and flavor development.

Fructose is used extensively in carbonated beverages/soft drinks, frozen desserts, baked goods, canned fruits, confectionery (chocolate, jellies, and gums), and diary products. Typical formulations include sports drinks and reduced-calorie beverages. Fructose has the ability to mask bitter and metallic tastes and aftertastes, especially with intense sweeteners [47]. Due to its extremely good solubility fructose is suitable for use in dry-mix beverages and desserts. Fructose is also more soluble in alcohol than sucrose, enabling the production of sweetened liqueurs with higher contents of dry substances [47]. Synergy with starches or other gel-forming products leads to increased gel strength and improved texture. Pharmaceutical uses include tablets or solutions for injections and infusions.

[Top of Page]

6. Quality Specifications and Legal Aspects

Fructose has been considered, like sucrose, to be de facto generally recognized as safe (GRAS). FAO-WHO Codex Alimentarius Commission [48], Food Chemicals Codex (FCC) [49], Council Directive 2001/111/EEC [50], European Pharmacopeia (E.P.4.05) [3], United States Pharmacopeia (U.S.P. XXVI) [51] define purity standards for crystalline fructose. The FAO-WHO Codex describes fructose as “purified and crystallized D-fructose with a fructose content of not less than

98 % m/m, and a glucose content of not more than 0.5 % m/m".

Only crystalline fructose is designated by the term "fructose". Dissolved in water it results in "fructose solution". A product of lesser purity, containing about 95 % fructose on total solids is referred to as "fructose syrup".

Fructose is regarded as a food ingredient, not an additive. In several countries it has the further status of sugar substitute and is permitted for sweetening foods for diabetics.

The composition and quality requirements for crystalline fructose in the Food Chemicals Codex are listed in Table 4 [49]:

Table 4. Fructose composition and quality requirements according to FCC.

Description*	
Assay**	
Arsenic (as As)	≤ 1 mg/kg
Chloride	≤ 0.018 %
Glucose	≤ 0.5 %
Heavy metals (as Pb)	≤ 5 mg/kg
Hydroxymethylfurfural	≤ 0.1 %, calculated on dried basis.
Lead	≤ 0.1 mg/kg
Loss on drying	≤ 0.5 %
Residue on ignition	≤ 0.5 %
Sulfate	≤ 0.025 %

* "Fructose occurs as white, hygroscopic, odourless, purified crystals or as a purified crystalline powder having a sweet taste. It is a natural constituent of fruit (hence, the name "fruit sugar") and is obtained from glucose in corn syrup by the use of glucose isomerase. Its density is about 1.6. It is soluble in methanol and in ethanol, freely soluble in water and insoluble in ether."

** "Not less than 98.0 % and not more than 102.0 % of fructose ($C_6H_{12}O_6$), after drying."

Typical composition of commercial grades of crystalline fructose is generally specified by the manufacturer (Table 5):

Table 5. Typical specification of crystalline fructose by manufacturer.

	Crystalline fructose
Solids, %	99.5
Moisture, %	≤ 0.5
Carbohydrate (dry solids basis), %	
Fructose	≥ 99.5
Dextrose	≤ 0.5
Oligosaccharides	trace to none
Ash, %	≤ 0.01
Heavy metals, mg/kg	<1 mg/kg

7. Analysis

Chromatographic methods are the most powerful analytical techniques for the analysis of fructose samples (raw material, food, production control, etc.) [52-55]. They allow the simultaneous analysis of the type and concentration of different kinds of saccharides in the sample. Thin layer chromatography (TLC) [56], high-performance liquid chromatography (HPLC), and high-performance anion exchange chromatography (HPAEC) with pulsed amperometric detection (PAD) [57], [58] are commonly used to separate and identify carbohydrates. Well-established for fructose determination is a HPLC system with strongly acidic cation exchanger in the calcium form as separation phase and water as eluent, or with amino-bonded phases with acetonitrile/water as eluent, using a refractive index (RI) detector. Gas chromatography (GC) is strongly recommended if impurities or minor components are of interest. GC can be applied after conversion of carbohydrates into volatile derivatives (e.g., oximation and subsequent trimethylsilylation) [59].

The determination of individual sugar contents in fresh fruits and vegetables and their juices is an important chemical analysis carried out to evaluate quality and to detect adulteration or contamination [60]. Up to now, analytical techniques such as liquid chromatography or enzymatic methods have become established [61], [62].

Chemical methods are based on the fact that fructose reacts as reducing agent. The principal methods are based upon the property of reducing alkaline solutions of certain metallic salts, especially alkaline copper solutions, and on the property of forming colored products with aromatic compounds in the presence of acid. The disadvantage of these reactions is the nonspecificity for fructose. Various carbohydrates can be detected and determined by these methods. In the reduction methods the reduced or unreduced copper can be determined by titration [63-65] (Lane-Eynon or the Luff-Schoorl procedure) or the reduced copper is determined gravimetrically [66]. The amount of reducing sugar, the fructose, is calculated from the required titer or the amount of reduced copper. An example for detection and determination of fructose by a colorimetric method is the reaction with anthron.

Fructose can be specifically determined by an enzymatic method, i.e., the hexokinase method [67], [68]. D-Fructose is phosporylated by hexokinase and adenosine-5′-triphosphate to D-fructose-6-phosphate, which is converted by phosphoglucose isomerase to D-glucose-6-phosphate. The glucose-6-phosphate is oxidized in the presence of the enzyme D-glucose-6-phosphate dehydrogenase by NADP to D-gluconate-6-phosphate. Reduced NADP (NADPH) is formed by the oxidation reaction and is measured photometrically by its characteristic absorbance at 340 nm. The amount of NADPH is equivalent to the amount of fructose. When the sample contains glucose, first the glucose must be determined by the hexokinase method. The enzymatic method is rapid, specific, and sensitive to low concentrations and is therefore ideal for determination of carbohydrates. Liquid foods can be tested directly, whereas solid foods have to be dissolved in water first. Enzyme assay kits for fructose-glucose-sucrose mixtures can be purchased commercially.

Physical methods like polarimetry, refractive index, IR, and density are commonly used. Polarimetry is a well established and quick method for purity testing. In the U.S.P. XXVI the polarimeter test is prescribed as assay for fructose determination. The concentration of carbohydrate in an unknown sample is determined by measuring its angle of rotation and comparing it with the calibration curve.

[Top of Page]

8. Storage and Handling

Crystalline fructose is a high-purity, free-flowing solid, which can be mixed with all types of dry ingredients. Storing and handling of crystalline fructose is determined by its chemical and physical characteristics. For handling and storage of crystalline fructose a maximum temperature of 25 °C and a relative humidity of ≤ 60 % [69] is recommended to prevent subsequent caking and flow problems. When stored and handled under the recommended conditions, crystalline fructose is shelf-stable and retains its free-flowing characteristics. Processing conditions should be controlled to avoid hardening and lumping problems. Most bagged fructose is packed in foil-lined paper bags to ensure minimal transfer of moisture to the product. Big bags are filled with up to 1000 kg of crystalline fructose.

Commercial fructose solutions with a dry matter content of 70 % are more resistant to microbial spoilage than equivalent concentrations of sucrose, owing to the greater osmotic pressure and the lower water activity [47]. It can be stored without any fear of crystallisation.

[Top of Page]

9. Trade Names

All commercial fructose products are characterized by the fructose content and residual other carbohydrates, which depend on the raw material: glucose from sucrose, fructooligosaccharides or glucose from chicory, and glucose, maltose, or oligosaccharides from starch.

Fructose as crystalline sweetener is often simply called “crystalline fructose” (e.g., Archer Daniels Midland, Südzucker). Liquid products with high purities (≥ 95 %) are also commercially successful.

Trade names include Krystar Liquid or Cristallin (Staley in the USA and Amylum in Europe, as part of the Tate & Lyle Group), Fructofin (Danisco), Fruisana (retail; Danisco), Fructose N (Amylum), Fruitose (Galam), fructose syrup CornSweet 95 (Archer Daniels Midland) and Fruchtzucker kristallin and Fruchtzuckersirup F 70/95 (Südzucker).

Fructose products derived from the hydrolysis of chicory inulin are produced and distributed by the Orafti Group. Their fructose syrup is named Raftisweet. Orafti is one of the four activity groups of Raffinerie Tirlemontoise which is part of the Südzucker group.

Products based on inulin from the producer Cosucra are named Fructoline L 85 (liquid), Fructoline L 95 (liquid) and Fructoline CR (crystallized). Frutasun, another high-fructose syrup based on chicory, is produced by Sensus.

[Top of Page]

10. Economic Aspects

Fructose is marketed as a healthy fruit sugar for added sweetness in low-calorie foods. Depending on the market functionality and/or nutritional aspects of fructose as a natural sweetener can be emphasised [70].

During the 1960s industrial quantities of crystalline fructose were produced in Europe with sucrose as raw material. Efforts in reducing production time and costs, especially in starch-based fructose production led to initial growth in the late 1980s. It was thought that crystalline fructose had the potential to make a breakthrough (as a sugar substitute) in granular uses similar to that which high-fructose corn syrup had achieved in liquid applications, notably the soft-drinks market. Until now, this has not proven to be the case.

Due to the complexity of the described production processes and the cost of the raw material this product is relatively expensive and is often viewed as a costly specialty caloric sweetener. However, over the last decade technological advances in corn-based sweetener processing techniques and chromatographic separation systems have lowered production costs.

The total sales of crystalline fructose are about 240 000 t worldwide. The largest producer of fructose has a stake of about half of the world production. The tonnage for total sales represents a little over 0.1 % of the global caloric sweetener market. In the years between 1985 and 1992, there was a strong growth of the crystalline fructose market. After several years crystalline fructose sales reached a plateau. The USA is the biggest producer and exporter of crystalline fructose. The largest amounts are sold to Canada, Japan, and the EU, the second largest market for crystalline fructose. Israel is permitted to export crystalline fructose to the EU under preferential trade agreement duty free. In the EU fructose syrups are very successful.

11. Physiological Properties

According to the structural classification of carbohydrates as suggested by the Food and Agriculture Organization and the World Health Organization (FAO/WHO) in 1998 fructose belongs to the group of sugars. Its energy value is specified by the EEC as 17 kJ/g (4 kcal/g) [71].

Ingestion of fructose is followed by its absorption in the small intestine as a consequence of facilitated diffusion mediated by Glut5, a member of the glucose transporter family. This absorption proceeds more slowly than the active absorption of glucose. Absorbed fructose enters the bloodstream via the portal vein, which transports it to the liver, where fructose is preferentially taken up. At high intakes, part of it (30–40 %) is rapidly metabolized in the intestinal mucosa to lactate, which passes to the liver and is transformed into glucose [72].

Fructose is metabolized by the human body fairly readily. Fructose metabolism (Fig. 4) involves the phosphorylation of fructose to fructose-1-phosphate by fructokinase (E.C. 2.7.1.3), cleavage of the resulting fructose 1-phosphate into dihydroxyacetone phosphate and D-glyceraldehyde by the liver isoenzyme of aldolase (E.C. 4.1.2.13) and phosphorylation of D-glyceraldehyde to its 3-phosphate by triose kinase (E.C. 2.7.1.28) [73].

Figure 4. Fructose metabolism.

The pathways of glucose and fructose metabolism in the liver converge at the triose phosphate stage as the glyceraldehyde-3-phosphate enters glycolysis or gluconeogenesis.

Thus, major products of fructose metabolism in the liver are glucose, glycogen, and lactate. Smaller quantities are oxidized to carbon dioxide, ketone bodies, or converted to triacylglycerol. Because the majority of the absorbed fructose is taken up by the liver and requires conversion to intermediates before entering the blood and undergoing metabolism, the effect of fructose on blood glucose level is very small [74].

Blood glucose levels following an oral fructose load are lower than after a comparable oral glucose load, i.e., fructose is a weakly glycemic carbohydrate. Thus, the glycemic index (GI) of fructose (using white bread as a standard) is only 32, which is explained by the partial conversion of fructose into glucose in the liver.

In addition, fructose has only a modest affect on the stimulation of insulin secretion, and uptake of fructose into the cells does not require the presence of insulin. Together with its weakly glycemic properties, this is why fructose is recommended as a dietary sweetener for diabetics, especially for people with non-insulin-dependent (type II) diabetes mellitus (NIDDM).

One of the most controversial areas in the dietary fructose literature is the effect of fructose on serum lipids and in particular on triglyceride levels. This issue has arisen because of alterations in plasma lipid concentrations following long-term excessive consumption of large amounts of carbohydrates, particularly fructose. The significance in humans is not clear and is still a matter of debate.

In hereditary fructose intolerance, a rare genetic defect, the absence of liver fructose 1-phosphate aldolase isoenzyme leads to an accumulation of fructose 1-phosphate in the liver [75]. Blockage of glycolysis and gluconeogenesis occurs and leads to hypoglycemia and eventually to hypoglycemic shock. Patients suffering from this disorder must avoid fructose in their diet.

1. Introduction

Energy conversion systems are the principal source of pollution on our planet. In the industrialized countries, the electric power plants which convert chemical energy in electrical energy are the main producers of CO_2 and SO_2 emissions, private cars, on the other hand, are the principal producers of CO and NO_x emissions. Figure 1 illustrates this situation for an industrialized country such as Germany (given for Western Germany in 1990) [1]. The concentration of CO_2 in the earth's atmosphere increased considerably since the last century as a consequence of industrialization [2] (see Fig. 2); it is considered the main reason for the greenhouse effect leading to an increase of the earth's surface temperature. Power plants and cars are important consumers of mineral oils and natural hydrocarbons, which have a higher potential as a raw material for the chemical industry than as fuel for, e.g., the production of electricity. Nowadays the air pollution and the diminution of the earth's resources of hydrocarbons are two main topics in politics and economics and regenerative energy sources are sought after. An alternative energy conversion technology such as the fuel cell technology offers many attractive possibilities for reducing both the air pollution and the indiscriminate destruction of precious chemicals. Fuel cells convert the chemical energy of a fuel such as methane directly into electrical energy with a better yield and much lower emission levels than any other energy conversion system [3], [4]. Although the principal operation of a fuel cell is known since the last century, the necessary technology for producing fuel cell systems of high efficiency, acceptable costs and at an industrial level has only been developed in the last few decades.

2. Principles of Fuel Cells

2.1. Functions

The principle operation of a fuel cell is comparable to that of a battery. In contrast to batteries – where the chemical energy is stored in substances inside the battery – fuel cells are just converting systems, the reagents have to be supplied continuously to the fuel cell in order to obtain electricity. Thus, fuel cells are systems which convert chemical energy directly into electricity in an invariant electrochemical set-up.

Figure 1. Emissions generated in Western Germany in 1990 with emphasis on power plants and road traffic in relation to overall emissions NMVOC = Non-methane volatile organic compounds

Figure 2. CO_2 concentration in the earth's atmosphere as a function of time [2]

Figure 3 schematically shows the principle of a fuel cell with a proton conducting electrolyte, hydrogen as fuel and oxygen as oxidant. Hydrogen and oxygen are supplied to porous electrodes, the gases reach the electrode – electrolyte interface and react such that water and an electrical current are produced.

A comparison between a fuel cell and a battery is shown in Figure 4. Batteries, both primary cells and rechargeable batteries, are best suited for smaller power requirements while fuel cells are more suited for larger power needs. In the 0.1 – 10 kW range an application of both systems may be possible depending on the specific conditions.

Figure 3. Sketch of the principal operation of a fuel cell: Two electrodes are separated by an gastight electrolyte. The fuel (H_2) is supplied at the anode, where it is oxidized releasing electrons. The oxidant (O_2) is supplied at the cathode, where it is reduced consuming electrons.

Because of the direct energy conversion fuel cells work at a higher efficiency than energy conversion processes which involve a conventional heating cycle. The latter are, therefore, limited

Figure 4. Comparison between two electrochemical devices – battery and fuel cell – for electricity production. A battery already contains the reagents, which have to be supplied to a fuel cell from an external reservoir.

by the Carnot's cycle. Figure 5 shows a comparison of the conversion routes of fossil fuels to electricity in a fuel cell and in a conventional system such as a heat engine. One obvious aspect is that fewer steps are involved in the fuel cell process than in the conventional process. In addition, the conventional process exhibits a lower conversion efficiency due to thermodynamic limitations. In a conventional process the chemical energy of fossil fuels is converted in electrical energy after several steps comprising a chemical reactor, mechanical engines and electrical generators, each step causes energy losses; a fuel cell can directly convert chemical energy in electrical energy, minimizing the losses.

This is illustrated in Figure 6 which compares the theoretical efficiencies as a function of temperature of a fuel cell supplied with pure hydrogen and pure oxygen and a Carnot process as the most efficient heat cycle operating between a heat reservoir at T and one at 300 K. Only at temperatures higher than 1000 °C is the efficiency of a Carnot process higher than that of a fuel cell. However, practical efficiencies of fuel cells remain higher even if the thermal cycles operate at much higher temperatures.

The efficiencies of the different energy conversion systems are compared in Figure 7 as a function of size of power plants. Figure 7 shows that the efficiencies of two types of fuel cell systems (phosphoric acid fuel cell, PAFC, see Section 3.1.3 and solid oxide fuel cell, SOFC, see Section 3.3.2) are higher than those of engines and conventional power plants of comparable size.

In addition to the high efficiency, fuel cells also exhibit an emission level, which is notably lower than present legal requirement, in Germany for instance, stipulated by "TA Luft". Fuel cells can convert up to 90 % of the energy of the fuel into electricity and heat, the electricity conversion efficiency is 45 % and higher, and the ratio between the electricity and the heat produced is about 1. The heat generated by a fuel cell can be used for producing hot water or steam. The highest temperature reached in a fuel cell is about 1000 °C which is the operating temperature of a solid oxide fuel cell. Even at this temperature, highly polluting nitrogen oxides are not produced, CO_2 is produced in reduced quantities, ashes and solid combustion products are not formed. Finally fuel cells themselves do not have moving mechanical parts, therefore they do not make noise.

2.2. Set-Up

The electrodes of a fuel cell exhibit a porous structure; through the pores fuel and oxidant

reach the so-called three-phase zones, where the reagents get in contact with both the catalyst deposited on the electrodes and the electrolyte. The reactions occur in these regions. Referring to Figure 3, the fuel (H_2) is oxidized at the anode, to form protons which move through the gas-impermeable electrolyte. At the cathode oxygen is reduced and water is produced, while electrons flow in an external circuit. Water is the only byproduct of the energy conversion in a hydrogen – oxygen fuel cell. This water is produced at the cathode in a fuel cell with proton-conducting electrolytes such as a proton exchange membrane or phosphoric acid, and at the anode in fuel cells with an alkaline electrolyte or an oxygen-ion conducting electrolyte such as yttrium stabilized zirconia.

Figure 5. Comparison between the two conversion routes of fossil fuel into electric energy. The chemical energy of the fuel is directly converted into electrical energy by fuel cells, in conventional systems the chemical energy of the fuels is converted first into thermal energy, than in mechanical energy and finally into electrical energy.
In the reformer hydrocarbons or methanol are converted to CO and H_2, according to $C_nH_m + n\,H_2O \longrightarrow n\,CO + (m+n/2)\,H_2$, or $CH_3OH + H_2O \longrightarrow CO_2 + 3\,H_2$

Figure 3 shows only the electrochemical core of a fuel cell. However, a single electrode – electrolyte assembly is not sufficient for electricity generation, since the typical voltage of a single cell is below 1 V. In order to obtain suitable voltages a number of cells are serially connected. Thus, in addition to the electrochemical components a fuel cell needs interconnector plates, which connect electrically two adjacent electrochemical units and usually also act as the reactant distributor. Several fuel cells connected by interconnectors form a stack. Such a stack is shown in Figure 8 for a fuel cell with polymer electrolyte.

Figure 6. Efficiency as a function of temperature of the energy conversion of a fuel cell and a conversion process limited by the Carnot's factor.

The supply of pure hydrogen and pure oxygen is not easy to realize, since no distribution system exists for these pure substances. For some niche applications, such as storage of regenerative energy, reactants in the form of pure hydrogen and oxygen may be available. In usual applications, a fuel cell should work with air as oxidant and with hydrogen produced in or near the system by reforming of other fuels. Typical reactions are reforming of hydrocarbons (e.g., methane) or alcohols (e.g., methanol) (see Section 3.1.2). Thus, a reformer is needed in the periphery of a fuel cell system. Operation with pure chemicals involves the advantages of working at low temperature and almost problem-free operation of the catalytic materials of the electrodes, whose performance depends strongly on the presence of impurities in the reagents. In recent years many efforts have been put into the

Figure 7. Efficiency of energy conversion as a function of the size of the power plant; conventional systems are compared with projected fuel cell systems such as PAFC and SOFC

improvement of the electrocatalysts and into the gas separation process after reforming in order to use cheaper and more common fuels and air in the fuel cell. A catalytic burner for the combustion of unreacted gases and a d.c./a.c. convertor also belong to the periphery of a fuel cell system, a more complete picture of a system for stationary electricity and heat generation is given in Figure 9.

Figure 9 shows a complete fuel cell system for stationary production of electricity and heat. Before being supplied to the fuel cell the fuel is compressed, heated, chemically processed in presence of water vapor (for example by reforming), the air is compressed and preheated. The residual gases after exploitation in the fuel cell stack for energy production are burned in a catalytic burner, which supplies the necessary heat for preheating and reforming. The residual heat is eventually removed from the system.

The materials used in a fuel cell must exhibit properties which can be generally summarized as:

The *electrolyte* has to have a high conductivity at operating temperature, i.e. it should cause a low ohmic drop ($< 0.15\ \Omega/\text{cm}^2$). It should have negligible electronic conductivity, be gas impermeable, and chemically stable in an oxidative and reductive environment (1.2 V and 0.0 V, respectively).

Figure 8. A Siemens PEMFC stack

The *electrodes* must have a high electrocatalytic activity for fuel oxidation or oxidant reduction, a high electrical conductivity (elec-

Figure 9. Fuel cell system for stationary production of electricity and heat
A complete fuel cell system comprises besides the electrochemical device other components such as gas compressors, reformers, catalytic burner, and d.c./a.c. converter.

tronic or mixed ionic and electronic), and must be chemically stable to reduction or oxidation and gas permeable.

The *interconnector* must have a high electronic conductivity and must be stable in oxidative environment on the cathode side and reductive environment on the anode side.

The *electrochemical system* interconnector – anode – electrolyte – cathode must exhibit high thermal stability to sufficiently withstand frequent thermal cycles, have a long operation life (5000 – 150 000 h, depending on application), be light, compact, not expensive, and easy to produce. In order to reach these targets, the design of the cell is of crucial importance, in fact, it can strongly affect the production costs and the efficiency of a fuel cell system. An important factor for the design is the dimension of the three-phase zones, where the electrochemical reactions take place. The three-phase zone has a thickness of just a few micrometers, therefore cell designs have to consider the design of the components (electrodes, electrolytes, and interconnectors) in such a way that the specific power density is increased by minimizing the volume of the stack for the same volume of the reaction zone.

Figure 10. Examples of current density – voltage curves for a solid oxide (see Section 3.3.2) fuel cell stack as a function of temperatures. These curves are measured directly. Parameter list: Interconnector $CrFe_5Y$; Anode Ni cermet ($Ni + ZrO_2$); Cathode lanthan strontium manganite (LSM); Electrolyte YSZ ($ZrO_2 - Y_2O_3$); Fuel H_2 (1 bar); Oxidant O_2/air (1 bar); stacks of 80 cells in serial connection

The usual way to characterize a fuel cell is to record the current density – voltage curve of single cells and stacks under different conditions of temperature, catalyst loading, reagent composition, concentration and pressure and to study how the curves vary with time in order to determine the possible operation time of cells

and stacks. From the current density – voltage curves the current density – power curve can be obtained which usually serves to compare different systems.

Examples of current density – voltage curves for a solid oxide fuel cell are given in Figure 10.

2.3. Efficiency

Another important parameter of a fuel cell is the efficiency of the conversion of the chemicals to electricity. This *electrical efficiency* is given by the product

$$\eta_{\mathrm{el}} = \eta_{\mathrm{id}} \ \eta_{\mathrm{U}} \ \eta_{\mathrm{F}} \ \mathrm{U}_{\mathrm{F}} \tag{1}$$

where the ideal efficiency $\eta_{\mathrm{id}} = \Delta G/\Delta H$ is the thermodynamic efficiency and corresponds to the total conversion of the free energy change, ΔG, to electrical energy in reference to the heating value of the fuel, ΔH.

The *voltage efficiency* $\eta_{\mathrm{U}} = U_{\mathrm{cell}}/U_{\mathrm{theoretic}}$ reflects voltage losses due to polarization phenomena at the electrodes and ohmic potential drops at the interfaces, in the electrolyte, and in the interconnectors (the theoretic cell voltage for water production is 1.23 V, voltages between 0.6 and 0.9 V are usually observed in real systems depending on current densities).

The *faradaic efficiency* $\eta_{\mathrm{F}} = I/I_{\mathrm{m}}$ is defined as ratio between the observed current and the theoretically expected current calculated on the basis of complete reaction. The faradaic efficiency is lower than 1 if a parallel reaction or chemical short circuit occur in the cell.

U_{F} is the utilization of the fuel in the cell or stack.

The electrical efficiency of the complete fuel cell system comprises also the efficiency of the periphery and is given by

$$\eta_{\mathrm{el}}^{\mathrm{system}} = \eta_{\mathrm{el}}^{\mathrm{stack}} \ \eta_{\mathrm{P}} \tag{2}$$

2.4. History and Development

The fuel cell history dates back to the 19th century. It began in 1839 with the experiments of the British scientist Grove, which were at that time just a laboratory curiosity [5]. Grove electrolyzed sulfuric acid using two platinum electrodes and noticed that the gases evolved (hydrogen and oxygen) were electrochemically active and provided a potential difference of ca. 1 V between the electrodes. Later Ostwald (1894) realized, on the basis of thermodynamic considerations, that an electrochemical cell can provide a higher energy conversion efficiency than heat engines, which are limited by Carnot's law [6].

At the turn of the century, eminent physicochemists like Nernst and Haber dedicated a lot of effort to the study of direct carbon-oxidizing fuel cells. The difficulty in obtaining appropriate materials at that time limited the success of their investigations. Baur proposed (for the first time in 1933) an electrochemical system working at room temperature, with alkaline electrolyte, using hydrogen as fuel [7]. Baur's proposal caught the attention of Bacon, a British engineer [8]. He successfully developed porous nickel electrodes in the 1950s and built the first high pressure, medium temperature alkaline fuel cell system in the kilowatt-range. Bacon's work was the basis of the later developed fuel cell for the NASA Apollo program.

Highly active porous metal electrodes with a dual porous structure like the Bacon electrodes were produced in the mid-1960s by Justi, Bishoff, Spenger, and Winsel in Germany, at the Technical University of Braunschweig [9]. These electrodes operated already at room temperature and at atmospheric pressure, and were based on pressed Raney nickel and Raney silver powder. The hydrogen and oxygen electrodes later developed at Varta and Siemens are based on this work.

In 1958, Broers [10] and Ketelaar, in Holland began to improve the high temperature molten carbonate fuel cell and achieved a longer life expectancy. Their research was based on the far earlier studies of Baur, Preiss (1938) and Davtyan (1946). Broers' work led to the present-day power plant systems which can oxidize hydrocarbon fuels directly, without a reforming step.

Aiming at low temperature air operation with low-cost carbon materials, other scientists in the 1950s continued the studies of Schmid, about gas diffusion electrodes (1923), of Berl (1943), about the peroxide mechanism of carbon-oxygen-electrodes and the work

on carbon – air electrodes by HEISE and SCHUMACHER (1932 – 1947).

KORDESCH and MARKO (University of Vienna) prepared special metal oxide catalysts (cobalt – aluminum spinels) for carbon electrodes (1951) [11]. The carbon tubes or plates were steam-activated to enlarge the active surface. The carbon – hydrogen electrodes contained small amounts of a platinum catalyst and could oxidize fuels such as alcohols and aldehydes directly at low temperature. These new carbon electrodes provided high current densities in alkaline electrolytes, at low temperatures, confirming BAUR's predictions of 1933.

Fuel cells experienced worldwide attention in the 1950s and the 1960s because of the "space race". Hydrogen – oxygen fuel cells were found to be the best choice for manned space flights not only because of their high energy density, but also because the reaction product is pure water that can be used by the crew for drinking and for cooling purposes.

After a short period of decline in the number of space projects, a new wave of fuel cell research and development (R & D) programs started in 1973 because of the oil crisis. Since then, investments in fuel cell projects have increased steadily, with more efficient energy conversion schemes and strong environmental control being demanded.

During the 1980s fuel cell R & D programs have spread out in many countries around the world. Large efforts are dedicated to the development of the technology of the five technically most promising systems: the alkaline, phosphoric acid, molten carbonate, solid oxide and the proton exchange membrane system (names referring to electrolytes).

3. Classification of Fuel Cell Systems

Fuel cell systems can be divided in two groups depending on the operation temperature. Low temperature fuel cells operate at a temperature lower than 250 °C, while high temperature fuel cells operate at a temperature above 600 °C. The fuel cell systems are usually classified and named after the electrolyte present in the cell, with one exception: the direct methanol fuel cell (DMFC) which is identified by the fuel used. Except for some alkaline fuel cells, a common characteristic of fuel cells is the use of an immobilized electrolyte, which means that the electrolyte is solid or consists of a liquid retained on a solid matrix. Immobilized electrolytes offer many practical advantages such as fewer corrosion problems, no leakage of the liquid, easier design, planning and construction. An overview of the material used for the components of the different fuel cell system is given in Table 1.

The other parameters such as reagents, temperature, pressure and application of the fuel cell system depend on the electrolyte in the cell. Table 2 lists these parameters for different types of fuel cells.

Several fuels can be used; depending on the type of systems they can be directly supplied to the anode or first undergo a reforming reaction. The thermodynamic efficiency of the combustion of different fuels are given in Figure 11.

The temperature dependence of the theoretical efficiencies $\Delta G^{o}/\Delta H^{o}$ of various reactions are plotted on the right scale. The corresponding cell voltages calculated from the Nernst equation are shown as well (left scale).

3.1. Low Temperature Fuel Cells

3.1.1. Alkaline Fuel Cells (AFC)

Alkaline fuel cells were the first type of fuel cells produced as a commercial product. The first alkaline fuel cell was build by BACON in the mid 1950s, it was a 5 kW system with 30 % aqueous KOH as electrolyte operating at 200 °C and 5 MPa, reactants were pure gases [8]. NASA used slightly modified Bacon cells for the Apollo program [12], the technical features of the Apollo fuel cells were: 85 % KOH as electrolyte, 230 °C operating temperature, 0.33 MPa pressure, pure gases as reagents, stack power 1.5 kW, and up to 11 000 h operation at the mission end. NASA improved the AFCs for the space shuttle program. The stack power was increased to 12 kW, the operating temperature lowered to 90 °C. They operated with pure gases and a specific power of 275 W/kg. Nickel plates were used as interconnectors, Pt – Pd mixtures were employed as anodic, Au – Pt mixtures as cathodic catalysts. Lifetimes up to 15 000 h were observed. In the 1970s many research projects on AFCs involved companies such as Union

Table 1. Materials used for the components of different fuel cell systems

Fuel cell	Electrolyte	Electrodes (anode/cathode)	Interconnector	Construction materials
Alkaline fuel cell (AFC)	conc. KOH in porous matrix	Ni/Ag (Pt/Pt) on porous Ni	Nickel	graphite, Inconel
Proton exchange membrane fuel cell (PEMFC)	proton exchange membrane	Pt on graphite	graphite sheet metal (stainless steel)	steel
Phosphoric acid fuel cell (PAFC)	conc. phosphoric acid in porous matrix	Pt/Pt	graphite	Inconel
Molten carbonate fuel cell (MCFC)	molten Li and K carbonate in porous matrix	Ni/NiO	Inconel	Inconel, Ni, ceramic
Solid Oxide fuel cell (SOFC)	yttrium stabilized zirconia ZrO_2 (Y_2O_3)	Ni cermet, $SrLaMnO_3$, other perovskites	chromium based alloys or chromium based ceramics	ceramic, Ni and Fe alloys

Table 2. Operating parameters of different types of fuel cells

Characteristic	AFC	PEMFC	PAFC	MCFC	SOFC
Temperature	60 – 90 °C	50 – 90 °C	160 – 220 °C	620 – 660 °C	800 – 1000 °C
Fuel	pure hydrogen	pure hydrogen, reformate ∗	pure hydrogen, reformate	natural gas, reformed or directly fed, biogas, coal gas	natural gas, reformed or directly fed, biogas, coal gas
Oxidant	pure oxygen	pure oxygen or air	air	air	air
Application	space and military	space, military, automotive, and stationary	cogeneration power plant	cogeneration or combined cycle power plants, depending on size	
System power at present		50 kW – 250 kW	11 MW	2 MW demonstration plant	100 kW demonstration plant
Electrical efficiency					
Stack	69 – 70 %	50 – 68 %	55 %	65 %	60 – 65 %
System	62 %	43 – 58 %	40 %	54 % (cogeneration) 60 – 65 % (combined cycle)	> 50 % (cogeneration) 65 – 70 % (combined cycle)

∗ Produced by reforming of hydrocarbons or methanol.

Figure 11. Thermodynamic equilibrium voltages and theoretical efficiencies for the combustion of different fuels in a solid oxide fuel cell

Carbide [13], Varta [14], Siemens [15], Elenco [16], and universities such as Graz [17], [18]. Siemens built an AFC with a power density of 12 kg/kW and current density of 0.4 A/cm^2 at 0.78 V [15]. The newest ACFs use immobilized electrolytes consisting of a porous matrix impregnated with 7 mol/L KOH; they work at temperatures $< 150\,°C$ [19].

The operating principles of an AFC comprise the following reactions:

$$H_2 + 2\,OH^- \rightarrow 2\,H_2O + 2\,e^-$$

(oxidation of the fuel at the anode)

$$1/2\,O_2 + 2\,e^- + H_2O \rightarrow 2\,OH^-$$

(reduction of the oxidant at the cathode)

The mobile ions are the OH^- ions of the alkaline solution which move from the cathode to the anode. The water is produced at the anode, it can be removed together with unreacted hydrogen or with the circulating electrolyte depending on stack design.

Reagents. The AFCs work only with pure reagents, the presence of impurities and nitrogen reduces the electrochemical efficiency of the cell. The presence of CO_2 which reacts easily with the alkaline electrolyte, to form carbonates may be detrimental for the cell, resulting in occlusion of the pores of the gas diffusion electrodes.

Electrodes. The AFCs use porous carbon electrodes, platinum is a typical catalyst for both the anodic and cathodic reaction, but also Ni and Ag are used for the anodic and the cathodic reactions, respectively [20]. The kinetics of both reactions, but especially of oxygen reduction, is favorable in the basic environment, the charge transfer overpotentials for the pure gases are less than 0.1 V for both electrode reactions.

Nickel is used as material for the *interconnectors*.

The operation temperature of an AFC depends on the electrolyte concentration but it is usually below 100 °C. The possibility to work at low temperatures and the use of pure gases allows the use of cheaper materials for electrodes and periphery. The pure gases allow for a dead-end configuration, where no gas outlets at the electrodes are necessary.

Although AFCs exhibit the highest electrical efficiency (60 %) of all fuel cell systems, their applications are limited to space and military programs, where high costs are permissible and pure hydrogen and pure oxygen can be supplied. The small regular amounts of CO_2 contained in air are sufficient to cause problems in the operation of a AFC, thus, air must be avoided. In spite of several attempts, operation with air was not successful, since even traces of CO_2 cause carbonate formation in the pores.

3.1.2. Proton Exchange Membrane Fuel Cells (PEMFC)

The PEMFCs are also known as *polymer electrolyte fuel cells* (PEFC), *ion exchange membrane fuel cells* (IEMFC) and *solid polymer electrolyte fuel cells* (SPEFC). The first prototype of PEMFC was produced by General Electric (GE) in 1963 [21]. A 1 kW system was realized for the Gemini mission of NASA with a sulfonated polystyrene membrane as electrolyte, the cell was operated with pure gases. In 1969 Nafion (Du Pont) was used as electrolyte in a GE fuel cell for the first time [22]. In the 1980s Ballard Power System began with a project on PEMFC and also used a proton exchange membrane produced by DOW Chemical [23]. A 5 cell stack using air as oxidant was presented in 1988; similar systems of varying power were used by Ballard [24] and by Daimler-Benz [25] in demonstration projects for the traction of buses and passenger cars since 1993.

The operating principles of a PEMFC comprise the following reactions:

$$H_2 \rightarrow 2\,H^+ + 2\,e^-$$ (oxidation of the fuel at the anode)

$$1/2\,O_2 + 2\,e^- + 2\,H^+ \rightarrow H_2O$$

(reduction of the oxidant at the cathode)

The mobile ions are the H^+ which move from the anode to the cathode, the water is produced at the cathode. Water is removed together with nitrogen and unreacted oxygen, if air is used as oxidant (see Fig. 12). The PEM single cell is often called *membrane – electrode assembly* (MEA).

Reagents. Air is generally used as oxidant, pure oxygen can also be used, with the possibility to have a dead-end configuration. The PEMFCs have been proposed for using hydrogen obtained from reforming of organic fuels

Figure 12. Proton exchange membrane fuel cell: the membrane – electrode assembly (MEA) consists of the Nafion membrane with the electrocatalyst on the surface in contact with porous carbon electrodes. Each MEA is mounted between two gas manifolds in an electrical insulating MEA frame and it is separated by an interconnector plate from the adjacent MEAs.

since the membrane is insensitive to CO_2. [The main problem in using hydrogen from a reformer is the presence of CO, which blocks the active sites of the Pt catalysts even at low concentrations (> 5 ppm).]

Figure 13. Current density – voltage curves of a PEMFC with Pt as electrocatalyst as a function of CO content of the fuel; the poisoning of the electrocatalyst is evident in the reduction of the voltage of the cell at constant current density. Anode: 1 mg/cm^2 Pt; Cathode: 1 mg/cm^2 Pt; Electrolyte: Nafion 117; $p(H_2)$: 2.2 bar (abs.); $p(O_2$:2.4 bar (abs.)

Electrodes. The porous electrodes consist of carbon cloths loaded with a mixture of platinum and Nafion. In order to achieve a good contact between the electrode, the catalyst and the electrolyte, the electrodes are pressed on the electrolyte membrane which acts as the supporting component. Other catalysts such as binary Pt – Ru mixtures and ternary systems such as Pt – Ru – Sn have been studied in view of a better CO tolerance [26]. Typical catalyst loadings are now below 0.5 mg/cm^2, but even lower loadings have been proposed [27]. The current density voltage curves of Figure 13 show the effect of CO on the performance of a cell with platinum as catalyst, Figure 14 shows the higher catalytic activity of Pt – Ru mixtures in presence of CO as compared with pure Pt. The positive effect of Ru is due to its ability to provide surface oxygen at low potentials; Figure 15 sketches the possible mechanism for the oxidation of CO on Ru which reduces the CO blocking of Pt and enables better hydrogen oxidation.

Graphite and stainless steel are used as materials for the *interconnectors*.

PEMFCs are characterized by the use of proton exchange membranes as electrolyte which are good electronic insulators and very good proton conductors in the presence of water.

Nafion (DuPont) has a fluorocarbon polymer backbone with fixed sulfonic groups (→ Fluorine Compounds, Organic, Chap. 8.1.4.). Nafion was developed in the 1960s by Grot as a separator membrane in chlor – alkali cells [22], it is until now the most frequently used membrane for this application, although it is expensive (and environmentally questionable because it is a fluorocarbon). Nafion membranes are produced as films with

thicknesses between 0.05 and 0.18 mm and different degree of sulfonation. They exhibit high mechanical and chemical stability and can be used as support for the porous electrodes, which can be applied by hot isostatic pressing onto the membrane [28]. A disadvantage of Nafion membranes is that their conductivity depends strongly on the water content of the membrane which is given by the ratio of number of water molecules per available number of sulfonic acid groups (see Fig. 16) [29]. If the membrane dries out, the ohmic drop becomes large and power and efficiency of the fuel cell decrease. The water content of proton exchange membranes depends on temperature, concentration of fixed charges, and the electro-osmostic drag, which causes the transport of water molecules with the proton migrating from the anode to the cathode during the operation of the fuel cell. Thus, the membrane can dry out on the anode side causing an increase in resistance of the electrical contact electrode – electrolyte because of the loss of ionic conductivity in the dry membrane. Water flooding of the pores can occur at the cathode. Both processes have to be avoided by a proper water management in the fuel cell, which comprises the use of humidified fuel gas.

Figure 14. Performance plots of PEM single cells with Pt, $Pt_{0.7}Ru_{0.3}$, and $Pt_{0.5}Ru_{0.5}$ anodes. The performance of different electrocatalysts in presence of CO in the fuel are shown as current density – power curves. Anode: 1 mg/cm^2 Pt or PtRu; Cathode: 1 mg/cm^2 Pt; Electrolyte: Nafion 117; Fuel gas: H_2 + 100 ppmv CO; Temperature: 80 °C; $p(H_2)$: 2.2 bar (abs.); $p(O_2)$: 2.4 bar (abs.)

Current densities of more than 1 A/cm^2 at 0.5 V have been observed at PEMFC with hydrogen as fuel and air as oxidant, even higher current densities can be obtained with pure oxygen as oxidant [30].

Figure 15. CO oxidation on a Pt – Ru catalyst. The presence of Ru in the catalyst composition causes a more facile oxidation of CO to CO_2 with removal of the adsorbed species from the catalytic sites.

Figure 16. Conductivity of Nafion 117 as a function of the water content of the membrane given as number of water molecules per sulfonic group. The conductivity of Nafion increases linearly with the water content.

In order to provide hydrogen *the reforming of a carbon containing fuel* may be necessary. The reactions of the reforming of hydrocarbons for the production of hydrogen are:

$$C_nH_m + nH_2O \rightarrow nCO + (m + n/2)H_2$$

$$CO + H_2O \rightarrow CO_2 + H_2$$

$$CO + 3\,H_2 \rightarrow CH_4 + H_2O$$

The steam reforming of methanol proceeds according to:

$$2\,CH_3OH + H_2O \rightleftharpoons 5\,H_2 + CO$$

$$CO + H_2O \rightleftharpoons H_2 + CO_2$$

The PEMFCs can also be used for *direct methanol conversion* (DMFC), in this case the following main reactions occur in the fuel cell:

Anode reaction $CH_3OH + H_2O \rightarrow CO_2 + 6\,H^+ + 6\,e^-$

Cathode reaction $3/2\,O_2 + 6\,H^+ + 6\,e^- \rightarrow 3\,H_2O$

The oxidation occurs in several steps, with the formation of adsorbed intermediate, such as –CHO or –CO on the catalyst. These adsorbates

Figure 17. Two different routes for using methanol as fuel for a fuel cell.

cause a deactivation of the catalyst with a consequent loss of cell efficiency. Depending on the electrolyte, a DMFC can work with a liquid methanol – water mixture at ca. 80 °C or with a gaseous mixture at higher temperatures.

A DMFC offers several advantages such as the absence of the reformer in the periphery of the system which reduces costs and increases efficiency. A comparison between a PEMCF and a DMFC is shown in Figure 17, which shows the two different way to supply methanol or other fuels such as natural gas to a low temperature fuel cell with proton exchange membrane as electrolyte.

The development of DMFC dates back to the 1920s when Müller studied the possibility of electrochemical oxidation of methanol [31], his results were the basis of the work of Kordesch and Makro, who tried to build a DMFC in 1951 [11]. In the 1960s, industrial research resulted in the construction of a 100 W – methanol oxygen fuel cell by Bosch in 1963 [32], with a faradaic efficiency of 50 – 60 %, and current densities of 50 – 100 mA/cm^2 at 0.4 V.

At the beginning of the 1980s, the interest for DMFC rose again and methanol was used as fuel for high temperature fuel cells [33]. Nowadays, PEM fuel cells with Nafion as electrolyte appear to be well suited for the direct oxidation of methanol. There are, however, some major problems in adapting a PEMFC to operate with methanol. The catalytic material of the anode has to be improved in order to avoid the loss of activity because of the formation of byproducts that block the active sites of the catalyst. As in the case of a PEMFC using hydrogen from a reformer as fuel, a method to improve the anodic material is the use of Pt – Ru or Pt – Ru – Sn mixtures [26]. A particular problem of the DMFC is cross-diffusion of methanol through the electrolyte. The methanol is then oxidized at the cathode which causes a reduction of the cell voltage, because of the mixed potential at the cathode due to methanol oxidation and oxygen reduction. In addition, the efficiency of the electrochemical system is reduced, because part of the fuel is oxidized without the production of electrons in the external circuit.

Another possibility of avoiding the poisoning of the catalysts is to operate at higher temperature as long as the electrolyte is stable and the cross over of methanol is tolerable. The interaction between Nafion and methanol is complex, methanol causes an increase of the ohmic drop of the membrane and a simultaneous modification of the pore structure of Nafion. Although the PEMFC is not yet optimized for direct methanol oxidation and the high efficiency obtained in a PEM with pure hydrogen as fuel is not yet reached (see Fig. 18), current densities of

400 mA/cm^2 at 0.5 V have been observed in a PEMFC at 130 °C for direct methanol oxidation [34].

Figure 18. Current density – voltage curves for PEMFC operating with hydrogen and methanol. The efficiency of a PEMFC operating as direct methanol fuel cell is about half of that of a PEMFC operating with pure hydrogen.

3.1.3. Phosphoric Acid Fuel Cells (PAFC)

In contrast to alkaline electrolytes, acid electrolytes tolerate CO_2, therefore, in the 1950s, fuel cells containing acid electrolytes have been proposed for the oxidation of hydrocarbons. After first attempts with sulfuric acid, the interest of researchers focused on phosphoric acid as electrolyte, and at the end of the 1960s the first PAFC was realized with the acid immobilized in a matrix. In the 1970s, several companies in USA and Europe tried to improve the PAFC technology, but only with the Japanese Moonlight program PAFCs became a commercial system. PAFC systems with a total capacity of 20 000 kW are currently operating in Japan. A 11 MW PAFC power plant has been built as pilot plant by Tokyo Electric Power Corporation, in cooperation with Toshiba and International Fuel Cells (IFC). Other important Japanese companies such as Fuji electric, Toyota and Mitsubishi are involved in fuel cell projects as manufacturers [4].

The operating principles of a PAFC comprise the following reactions:

$$H_2 \rightarrow 2\,H^+ + 2\,e^- \text{ (oxidation of the fuel at the anode)}$$

$$1/2\,O_2 + 2\,e^- + 2\,H^+ \rightarrow H_2O$$

(reduction of the oxidant at the cathode, air is the most common oxidant)

The mobile ions are the H^+ which move from the anode to the cathode through 100 % phosphoric acid immobilized in a SiC – poly(tetrafluoroethylene) (PTFE) matrix, the water is produced at the cathode, it is removed with nitrogen and unreacted oxygen.

Reagents. Air is used as oxidant and hydrogen obtained by reforming of hydrocarbons such as natural gas, as fuel.

Electrodes. Graphite paper is used for the porous carbon electrodes and the catalyst is a mixture of platinum and PTFE based resin, for the use of $CO + H_2$ mixtures (reformate) Pt – Ru is used as catalyst for the anodic reaction.

Graphite is the material of the *interconnectors*.

The phosphoric acid fuel cell works at a temperature between 160 and 220 °C, the CO contamination of the catalysts is rather low at these temperatures; up to 1 % CO are tolerated in the feed gas. The conversion efficiency of a complete PAFC system is ca. 40 %, the emissions of a PAFC systems are much lower than the emissions caused by a gas engine and far below the emission limits stipulated by law in Germany (TA Luft), (see Fig. 19).

3.2. Intermediate Temperature Fuel Cells

No fuel cell system has been developed up to now working in a temperature range between 250 °C and 600 °C, although this range is favorable for some applications. Waste heat is obtained at a temperature level where it can be used for methanol reforming. In other applications high grade heat may be available without having the material problems of high temperature fuel cells. The main problem seems to be the development of a suitable electrolyte.

3.3. High Temperature Fuel Cells

3.3.1. Molten Carbonate Fuel Cells (MCFC)

The development of molten carbonate fuel cells started in 1951, when Boers and Ketlaar built a fuel cell with a mixture of sodium carbonate and tungsten oxide as electrolyte; later they changed it to a mixture of lithium, sodium, and

Figure 19. Comparison of emissions of a cogeneration plant with a gas engine and with a phosphoric acid fuel cell
VOC = volatile organic compounds

potassium carbonate in a sintered MgO matrix [10]. Such mixtures exhibit high ionic conductivities at about 700 °C. Fuel cells with circulating molten carbonate were built in the 1960s, when also the partial oxidation concept (POC) for the reformer was introduced with about 70 % efficiency of the energy conversion. In the field of energy conversion, partial oxidation means understoichiometric thermal or catalytic combustion of hydrocarbons or alcohols with oxygen from air in a reformer.

Theoretical (stoichiometric) conversion for the exothermic hydrogen production is as follows:

$$C_mH_n + m\,O_2 \longrightarrow m\,CO_2 + n/2\,H_2$$

$$C_mH_{2m+1}OH + (m-0.5)\,O_2 \longrightarrow m\,CO_2 + (m+1)\,H_2$$

The produced gas contains 20 – 40 vol % H_2, with large amounts of nitrogen (up to 50 vol %), water and carbon oxides.

In 2000 several projects on MCFC are being developed in USA, Japan, and Europe. Energy Research Corp. (ERC) and M-C Power Corporation are working on a MCFC plant with a power output of 2 MW/a; which are supposed to commercialize 500 kW to 3 MW systems. Mitsubishi, Fuji and Hitachi in Japan are involved in MCFC projects, cells of an area of about 1 m^2 are planned. Italian Ansaldo, Dutch ECN, and German MTU formed a development consortium for MCFC systems.

The operating principles of a MCFC comprise the following reactions:

$$H_2 + CO_3^{2-} \rightarrow H_2O + CO_2 + 2\,e^-$$

(oxidation of the fuel at the anode)

$$1/2\,O_2 + CO_2 + 2\,e^- \rightarrow CO_3^{2-}$$

(reduction of the oxidant at the cathode, air is the most common oxidant)

The mobile ions are CO_3^{2-} ions which move from the cathode to the anode through the molten Li, K, and Na carbonates immobilized in a MgO matrix, the water is produced at the anode. Water is removed together with CO_2, possible traces of CO react at the anode with H_2O, forming CO_2 and H_2. Therefore, it is very convenient to use MCFC with fuels such as natural gas or other hydrocarbons.

CO_2 needs to be recycled in order to keep the electrolyte composition constant, CO_2 is formed at the anode and has to be supplied at the cathode with the oxygen.

Reagents. Hydrogen, reformed alcohols, or hydrocarbons are used as fuel, oxygen or air as oxidant.

Electrodes. The electrocatalytic material of a MCFC is nickel. The cathode becomes oxidized and lithiated during the first hours of operation. Nickel oxide is soluble in molten carbonates, thus in the course of operation two undesirable effects may occur: (1) metallic nickel particles

Figure 20. Methane reforming reaction at the anode of a molten carbonate fuel cell. The reaction between fuel and water takes place in the outer part of the anode, the produced hydrogen reacts at the interface anode – electrolyte.

are formed in the electrolyte which can lead to an electronic short circuit of the electrodes, (2) the size of the cathode diminishes. Two approaches have been proposed for solving these problems: the use of less corrosive molten carbonate mixtures and more stable cathodes containing iron and cobalt. The nickel anodes usually contain chromium which promotes the sintering process.

Inconel is used for the *interconnectors*.

The molten carbonate fuel cells work at ca. 650 °C, this temperature requires special materials stable at such high temperatures and towards corrosion, which is severe at this temperature. The electrocatalysts are mixed with ceramic materials and the cathode acts as the supporting element in MCFC. The cathode has the structure of sintered porous tiles, the electrolyte is produced by a tape cast technique, the anodic material is like a paste and is deposited on the electrolyte.

Molten carbonate fuel cells do not need external reforming of methane, reforming takes place at the anode of the fuel cell. The reactions occurring at the anode are as follows (see Fig. 20):

$$CH_4 + H_2O \rightarrow 3\,H_2 + CO$$

$$3\,H_2 + 2\,CO_3^{2-} \rightarrow 3\,H_2O + 3\,CO_2 + 6\,e^-$$

$$CO + CO_3^{2-} \rightarrow 2\,CO_2 + 2\,e^- \text{ (minor side reaction)}$$

The internal reforming takes place at temperatures of about 650 °C, which is lower than the usual temperature of a reformer (about 800 °C). The conversion, however, is fast enough, moreover it is not necessary to supply heat for the external reformer, since the heat for the internal reforming is provided by the heat losses of the reactions in the fuel cell. In this way the internal reforming works as a heat sink which helps to reduce the size of the heat exchanger in the power plant. Advantages and problems of internal reforming referring to higher temperature fuel cells in general are summarized below:

Advantages. The efficiency of the power plant increases with increasing degree of internal methane reforming from 2 at 50 % internal reforming to 8 at 99 % internal reforming.
Disadvantages. The H_2 producing endothermic reforming reaction is much faster than the H_2 consuming electrochemical oxidation; temperature gradients cause material problems; a sharp cooling effect occurs at the cell inlet.

3.3.2. Solid Oxide Fuel Cells (SOFC)

Solid oxide fuel cells have experienced a recent renaissance. The most common solid oxide, which is used as electrolyte in SOFC, is a mixture of zirconia and yttria, which is very similar to the Nernst mixture, an oxide studied by Nernst at the beginning of the century because of its ionic conductivity [35]. Yttrium stabilized zirconia (YSZ) contains between 8 and 10 mol % yttrium and has a stable cubic structure; it is an oxide ion conductor with a sufficiently high conductivity at temperatures around 1000 °C. This is an advantage for the direct oxidation of fuels

Figure 21. Structure of the three-phase zones at anode and cathode of a solid oxide fuel cell

in the fuel cell, but is a very challenging temperature for any material. Thermodynamics predict an efficiency of 80 %. A further advantage of the high operation temperature is the possibility to efficiently use the waste heat in a combined cycle power plant.

SOFC developing programs are carried out by Siemens – Westinghouse [36], Allied – Signal, Mitsubishi, Fuji Electric, and Sulzer.

The operating principles of a SOFC comprise the following reactions:

$$H_2 + O^{2-} \rightarrow H_2O + 2\,e^-$$

(oxidation of the fuel at the anode)

$$1/2\,O_2 + 2\,e^- \rightarrow O^{2-}$$

(reduction of the oxidant at the cathode)

The mobile O^{2-} ions in YSZ move from the cathode to the anode, the water is produced at the anode, it can be removed together with unreacted hydrogen and CO_2 (in the case of hydrocarbon combustion). For internal reforming the anode reaction also provides the necessary water for steam reforming. The operation principles of a SOFC with YSZ as electrolyte is shown in Figure 21.

Gd-doped CeO_2 has been proposed by several researchers as electrolyte with high conductivity at lower temperatures; gallates have also investigated. The Arrhenius plots of the ionic conductivity of some mixed oxides are shown in Figure 22 [37].

Figure 22. Arrhenius plots of the conductivity of several oxides, which exhibit high ionic conductivity and could be suitable electrolytes for SOFC

Reagents. Any kinds of fuels and oxidants are suitable, no reformer is needed for methane, the reagents can be directly supplied to the cell.

Electrodes. The anodes of SOFC consist of Ni cermet, a composite of metallic Ni and YSZ, Ni provides the high electrical conductivity and catalytic activity, zirconia provides the mechanical, thermal, and chemical stability. In addition, it confers to the anode the same expansion coefficient of the electrolyte and renders compatible

anode and electrolyte. The electrical conductivity of such anodes which is predominantly electronic, is shown in Figure 23 as a function of the nickel content, while Figure 24 shows the three-phase boundary at the interface porous anode YSZ and the reactions which take place. The cathode of the SOFC consists of mixed conductive oxides with perovskite crystalline structure. Sr doped lanthanum manganite is mostly used, it is a good *p*-type conductor and can contain noble metals.

Figure 23. Electrical conductivity of Ni cermet, the anodic material of SOFC
$T = 1000\,°C$; $T_s = 1300\,°C$

Interconnectors. A ceramic consisting of lanthanum chromite or a chromium based alloy are normally used; austenitic steel is also suitable at $T < 850\,°C$.

The high operating temperature of SOFC renders crucial the choice of the materials, which have to possess not only the abovementioned typical features but also a very similar expansion coefficient in order to allow for thermal cycling. Thus, only a few materials can sustain the working conditions of SOFC without significant changes after long term operation. Most of the materials used in SOFC are relatively expensive. The expected high efficiency of a SOFC is quite attractive and many cell designs have been proposed. Many attempts have also been made to lower the operating temperature in order to reduce the demands on the materials.

Three designs for SOFC stacks are described below:

Figure 24. Anodic reactions at the three-phase boundary of a SOFC
$V_O^{\circ\circ}$ = oxygen vacancy in solid conducting oxide

Figure 25. Tubular SOFC stack concept of Westinghouse
Advantages: No sealing; Disadvantages: Ohmic loses, low power density

Tubular Design of Westinghouse. Figure 25 shows the principles of the tubular design developed by Westinghouse. A single cell has the form of a long tube. The tube consists of a porous ceramic substrate, usually on zirconia basis. The components of the electrochemical cell are deposited on the tubular support, starting with the cathode. The electrolyte is deposited on the cathode, but the cathode is not completely covered by the electrolyte material, a strip of cathodic material is covered by the interconnector material for the electrical connection of the cathode. The anode is deposited on the electrolyte.

Figure 26. Conventional flat-plate (Siemens, left) and planar (Research Center Jülich, Germany, right) SOFC stack concepts

Several tubes are arranged in a case separated by nickel felts, air is supplied inside the tubes, the fuel is supplied outside the tubes.

The manufacturing of the tubular cells is relatively easy, the subsequent depositions of the electrode materials occur by simple coating and masking techniques, the gastight materials of electrolyte and of interconnector are more difficult to obtain and more sophisticated techniques such as plasma spray or electrochemical vapor deposition are necessary, which are rather expensive manufacturing techniques.

The main advantage of the tubular design is the absence of sealing in the stack. Westinghouse built a 25 kW stack and tested single cells up to 40 000 h. Currently a 100 kW demonstration power plant is being operated in the Netherlands.

Planar Designs.

Siemens Concept (Fig. 26, left). The planar concept of SOFC developed by Siemens is similar to the sandwich structure of the PEM single cell (see Figs. 8 and 12), a foil of YSZ with thickness of 150 – 200 µm acts as the supporting component on which the electrode materials are deposited, the single cells are then stacked with interconnectors with the gas channels and sealing elements in between. The gases can be supplied in co-, cross- or counterflow and can be let to and out the stack in internal or external manifolding. The differences in the gas management cause different temperature pattern in the single cells and in the stack. The thickness of the electrolyte, which is defined by the necessary mechanical stability, causes ohmic losses and renders it difficult to reduce the operating temperature considerably below 900 °C. Another disadvantage of this type of planar cell is the relative small size of the single cell (commonly $5 \times 5\,cm^2$, $10 \times 10\,cm^2$ possible), which is mainly due to the difficulty to cast large uniform ceramic foils and the necessity to increase the thickness of the electrolyte in the case of larger cells which results in higher ohmic losses.

Other developers also use the flat cell concept which was recently discontinued by Siemens because of the merge with Westinghouse.

IEV Concept (Fig. 26, right). In the planar SOFC developed by IEV-Forschungszentrum Jülich the anode is chosen as the supporting element [38]. In this cell, the anode has a thickness of approximately 1 mm, electrolyte and cathode are deposited in 2 – 10 µm and 40 – 50 µm thick layers, respectively, on the anode. The anode exhibits a varying composition. Typical characteristics of the anode are (Fig. 27): the reforming reactions occur in the outer layer of the anode, the central part of the anode has a high electronic conductivity and high porosity, the electrochemical reactions take places as usual at the interface with the electrolyte. This planar concept overcomes the disadvantages of the first planar concept (Siemens), it is, in fact, possible to work at lower temperature (< 700 °C) and to produce

Figure 27. Model of the multi-zones of a substrate anode.

large single cells ($25 \times 25\,cm^2$). In addition, the reaction zones for reforming methane and electrochemically oxidizing the resulting hydrogen are spatially separated and can be optimized separately.

Figure 28. Sketch of the electric car Necar III developed by Daimler-Benz

4. Examples of Application of Fuel Cells

4.1. Zero Emission Vehicle

Demonstration cars equipped with fuel cells were produced already in the 1960s in USA by Union Carbide and Allis Chalmers, and in Europe by Siemens and VARTA, the fuel cells used in these vehicles were alkaline fuel cells. Since the beginning of the 1990s fuel cell cars have become again very attractive because they offer the possibility to reduce the engine emissions. Two of the most relevant projects on zero emission cars are carried out in Canada by Ballard and in Europe by Daimler-Benz. Both projects use PEMFCs. Beside other advantages PEMFCs exhibit a more advantageous weight : power ratio than AFCs of about 2 kg/kW vs. 15 kg/kW, the former is similar to combustion engine values. Ballard and Daimler tend to use methanol as fuel and air as oxidant. In the first stage, methanol will be reformed to hydrogen. However, the possibility of using a DMFC is not excluded, since it would have several advantages such as reducing the size and the weight of the system because of the elimination of the reformer and of the shift reactor necessary for the CO removal.

In 1993 the costs of a drive train for an electric car furnished with fuel cells are about 10 times higher than those for a conventional one (150 – 260 €/kW) [39]. However, the prices of fuel cells are supposed to decrease rapidly in the next years. The first Daimler-Benz car was a van named NECAR (new electric car), which was presented to the public in 1994. The van was mostly occupied by the fuel cell and by the hydrogen tank. In 1996 NECAR II was presented, NECAR II is also a van which seats six to eight passengers, has a compact fuel cell and the hydrogen tank on the roof. NECAR II can reach 110 km/h and can travel up to 250 km without refueling.

Necar III is a small car (Mercedes A-Klasse) with a PEMFC for indirect methanol combus-

Figure 29. Phosphoric acid fuel cell cogeneration system PC 25 developed by ONSI and tested by Thyssengas

Figure 30. Block diagram of the energy generation and storage system for the energy autonomous house developed by FhG-ISE, Germany

tion with a methanol reformer and a gas clean-up system. Figure 28 shows the main features of the vehicle [40].

4.2. PAFC Power Plants

Cogeneration plants simultaneously produce electricity and heat in the form of steam or hot water. Fuel cells are suitable for being used in such systems, especially with natural gas as fuel. The advantage of natural gas is the low emission and the high energy content. An example of a cogeneration plant with PAFC is shown in Figure 29 [41]. This system comprises a reformer for the production of hydrogen from natural gas and a shift reactor for the removal of carbon monoxide down to ca. 1 % from the gas mixture to be supplied to the fuel cell. The fuel cell of this system is a phosphoric acid fuel cell stack PC 25 A, produced by ONSI Inc.; it has a maximum electric power of 200 kW and a maximum thermal power of 220 kW. The electric efficiency of the stack is about 40 %. PC 25 A are applied in several countries for on-site energy production and are the first fuel cell systems commercially available.

4.3. Regenerative Systems

Fuel cells can also be used in regenerative systems as a component of a long term energy storage system. An example of this application is the energy autonomous house in Freiburg, Germany, a project of the Fraunhofer Society. The house is a solar, independent, emission-free electricity source, which can work continuously throughout the year because of an electrochemical storage system. It comprises a photovoltaic solar

system for the conversion of light into electricity, the produced electricity which is not immediately used, can be stored in batteries for day-to-day fluctuation of the power requirements. For seasonal storage (store in the summer use in the winter) an electrolyzer is employed for the production of hydrogen and oxygen. The highly pure gases can be stored and later supplied to a fuel cell for the production of electricity (see Fig. 30) [42]. The quality of the gases allows the application of any low temperature fuel cell such as AFC or PEMFC.

1. Introduction

This article is concerned only with fungicides used in agriculture. Fungicides for human and veterinary therapy are described in → Antimycotics, → Dermatotherapeutic Agents. For the use of fungicides in the protection of wood and other materials, see → Biocides; → Wood, Surface Treatment and → Wood, Preservation.

Agricultural fungicides are chemicals that are used to prevent or minimize crop losses caused by phytopathogenic fungi. Successful compounds must be sufficiently fungitoxic at doses that are well tolerated by the crop. De-

pending upon the concentration of the fungicide, its activity may be *fungistatic,* i.e., fungal growth is only temporarily inhibited in its presence, or it may be *fungicidal,* i.e., the fungus is killed on contact.

Fungal plant diseases frequently develop during periods of high humidity accompanied by favorable temperatures; thus the period of most intensive fungicide use generally coincides with the onset of the rainy summer season. This is particularly true for fungicides that are sprayed to protect foliage and fruit of the growing crop. The use of fungicides in seed and postharvest treatment is a relatively low-cost method of preventing crop loss, even in situations where the risk is considered to be low.

2. Phytopathogenic Fungi

Plant diseases may be induced by noninfectious or by infectious agents. Noninfectious diseases can arise as a result of unfavorable environmental factors (e.g., temperature extremes, poor water relations, a deficiency or excess of minerals). Infectious diseases are caused by living organisms including fungi, bacteria, viruses and nematodes that can be transmitted to healthy plants.

Biology of Fungi. (See also → Biotechnology, Chap. 1.3.2.). Fungi are considered to be primitive (eukaryotic) microorganisms that lack chlorophyll. The body (thallus) of the fungus usually consists of branched threads (hyphae) which form a network (mycelium). The hyphae may be divided into cells by cross-walls (septae). Reproduction and dispersal take place by means of asexually or sexually produced spores that are borne directly on the hyphae or are produced in fruiting bodies. Asexually produced spores (in conidia, sporangia) are usually formed in large numbers and generally cannot survive under unfavorable environmental conditions (e.g., temperature extremes or low humidity). Their function is to ensure rapid dissemination of the fungus and colonization of new hosts. Sexually produced spores (e.g., oospores, ascospores, basidiospores), on the other hand, usually ensure the survival of the fungus under adverse weather conditions in the absence of a suitable host. The asexual part of the life cycle is referred to as the imperfect stage whilst the sexual phase is referred to as the perfect stage.

Classification. Because the spectrum of activity of fungicides can often be linked to the taxonomic grouping of the fungi, a basic understanding of the classification system is necessary when discussing activity. Fungi are classified on the basis of the type of spore or fruiting body they produce and are divided into four major classes: Oomycetes, Ascomycetes, Basidiomycetes, and Deuteromycetes. (In Deuteromycetes the perfect stage is not known.) Not only are the spore forms and life cycles of the fungi in these classes very different, the composition of their cell walls and their metabolic pathways also vary considerably. Examples of some important plant pathogens in the four major classes are given below.

Oomycetes include the downy mildews, late blights, white rusts, and root and collar rots caused by two soil-borne genera *Pythium* and *Phytophthora.* Important examples are

Phytophthora infestans, late blight of potato and tomato
Plasmopara viticola, downy mildew of grape vine
Phytophthora nicotianae var. *nicotianae*, tobacco black shank
Peronosclerospora sorghi, maize and sorghum downy mildew
Pythium ultimum, seedling damping-off of various crops

Ascomycetes include the powdery mildews and anthracnoses, as well as various leaf and fruit spot diseases. Important examples are

Erysiphe graminis, powdery mildew of cereals
Podosphaera leuchotricha, powdery mildew of apples
Venturia inaequalis, apple scab
Sclerotinia fructicola, brown rot of stone fruit
Gaeumannomyces graminis, take-all of cereals

Basidiomycetes include the true rusts, smuts, and bunts. Important examples are

Puccinia triticina, brown rust of wheat

Puccinia striiformis, yellow smut of cereals
Tilletia caries, wheat bunt
Pellicularia oryzae, rice sheath blight

Deuteromycetes is a large group of plant pathogens responsible for leaf and fruit spots, among others. Important examples are

Pyricularia oryzae, rice blast
Botrytis cinerea, grey mold of grapes
Alternaria solani, early blight of tomatoes
Cercospora arachidicola, leaf spot of groundnuts
Fusarium oxysporum, Panama disease of bananas

Mode of Action. Phytopathogenic fungi attack higher plants to obtain nutrients for their own growth and reproduction, i.e., they are parasitic. *Facultative parasitic fungi* (e.g., *Pythium ultimum*) are able to grow on both living plant material and nonliving substrates. They invade and kill host tissue by producing enzymes or toxins. *Obligate parasites,* such as rusts, are only able to obtain nutrients from living hosts; they are adapted to carry out this function, without killing the plant outright.

All plant parts are liable to fungal attack, and the symptoms can be expressed in many forms such as wilt, rot, blight, or mildew. Because these terms describe only the symptom and not the causal agent of the disease, the pathogen must often be isolated from the diseased material and identified before a diagnosis can be made. Once the pathogen has been identified, a knowledge of its life cycle and epidemiology provides an appropriate basis for selecting

1) the most appropriate time to implement chemical control measures
2) the method of application, and
3) the most suitable fungicide.

Crop Losses. (See also → Crop Protection.) The damage that fungi cause to agricultural crops may be of a quantitative or a qualitative nature. Diseases caused by Oomycetes tend to be "explosive" and, under appropriate conditions, can result in total crop loss within a matter of weeks (e.g., potato late blight). In regions where such diseases pose a threat, protective fungicide sprays must be applied routinely before disease symptoms appear.

Other fungi may not cause total crop loss but may produce leaf lesions or necrosis which reduces the photosynthetic leaf area. This can lead to premature senescence of the foliage and decreased yield (e.g., *Cercospora* leaf spot of groundnuts). The timing of fungicide application is not as critical in this case and the decision might be taken to delay spraying until the disease is first reported in a particular region.

The economic effects of a disease such as powdery mildew of apples may not be obvious at first, particularly under conditions of moderate disease pressure. In the long term, however, failure to implement suitable control measures leads to a decline in the vigor of affected plants, which results ultimately in death.

Qualitative damage is caused by diseases that affect the appearance of the marketed crop (e.g., apple scab). Lesions may be superficial and not affect deeper tissues, but blemished fruit is sharply downgraded and the grower then receives a much lower price. A strict, preventative fungicide spray regime should, therefore, be followed to prevent economic losses.

3. Types of Fungicide and Mechanism of Action

Fungicides can be divided conveniently into nonsystemic and systemic types, although some overlap occurs with compounds that have a local penetrating effect.

Nonsystemic fungicides (also called contact or residual protective fungicides) do not penetrate the plant tissues. They form a protective barrier on the plant surface and prevent the fungus from entering the host by inhibiting spore germination or mycelial growth. They only serve a protective function. Most nonsystemic fungicides react with thiol groups that are present in the enzymes of the fungus and so inhibit many metabolic processes. They are therefore considered as multisite inhibitors.

Systemic fungicides enter plant tissues and are transported in the plant sap. They may be transported upward (i.e., acropetal translocation) or downward, from leaves to roots (i.e., basipetal translocation). These compounds usually inhibit fungal growth after the pathogen has penetrated the host tissues; thus, they have curative properties. The spectrum of activity may be

narrow and confined to specific types of fungi, as in the case of ethirimol and powdery mildew, but it may also be relatively broad as in the case of the triazoles. Systemic fungicides generally interfere with biosynthetic processes (e.g., respiration, protein synthesis, membrane functions) and are specific-site inhibitors. They inhibit fungal growth and spore production more effectively than spore germination.

Locally systemic fungicides penetrate into the plant tissue but are not transported in the plant sap.

The earliest nonsystemic fungicides were inorganic and based on either sulfur or copper. Later, organic mercury compounds were introduced for seed treatment. Fungicides based on these three elements are still important, although mercury based compounds are being replaced gradually by safer, more environmentally acceptable chemicals.

From the 1930s to the late 1960s, many new organic compounds with fungicidal activity were discovered. Of great importance was the discovery of dithiocarbamates in 1934, which finally led to the patenting of mancozeb in 1964. Other major fungicide types discovered during this period include chlorothalonil and the phthalimides, which are still important today.

Modern systemic fungicides were discovered in the mid- to late 1960s when activity against rice diseases was detected in organophosphorus compounds. In 1967, a new group of broad-spectrum fungicides, the benzimidazoles, was discovered. This was followed quickly by the identification of several major new groups including carboxanilides, pyrimidines, morpholines, and antifungal antibiotics. In the 1970s, further breakthroughs occurred with the identification of phenylamides, ethyl phosphite triazoles, and strobilurins.

The action of fungicides may be described as

1) *curative:* the fungicide is able to stop pathogen development during the incubation period (the time from when infection occurs to the appearance of first symptoms)
2) *eradicative:* the fungicide is able to stop the progress of the disease after the appearance of symptoms
3) *protective:* the fungicide prevents infection (penetration into the plant) from taking place. It should be present on the plant surface before spore germination occurs.

Systemic fungicides have resulted in considerable progress in the standards of disease control in crops. Compared to nonsystemic fungicides, significantly smaller amounts are needed per hectare at less frequent intervals. Because systemic fungicides inhibit fungal growth inside plant tissues, they can be used curatively or even eradicatively. However, the spectrum of diseases controlled by certain systemic fungicides is narrow, and some fungi are prone to development of resistance (cf. Chap. 5).

Quantitative analysis of most agricultural fungicides relies on HPLC and GC. A description of these methods is, however, beyond the scope of this article; for details, see [9].

Some older fungicides are no longer in use and have therefore been omitted from this update, e.g., Chloroneb, Anizaline, Dichlone, Phosdiphen, SSF-109, ICIA 0001, Furmecyclox, Pyracarbolid, Ethoxyquin. Other older fungicides which are no longer under patent protection are still listed in this edition because they are marketed as generics by different companies or used in combination products. Only a selection of trade names is given for each fungicide.

4. Method of Fungicide Application

Because of the close association between pathogenic fungi and their hosts, fungal diseases are often more difficult to control than insect pests, which are more obvious and accessible targets. To be effective, fungicides must come into contact with the pathogen and, especially in the case of nonsystemic compounds, must be distributed uniformly on the surface of all susceptible plant parts so as to form a protective barrier.

The efficiency of the fungicide is influenced by the type of equipment that is chosen for its application. Likewise, the formulation can influence retention and persistence of the chemical on the target surface.

Plants are treated with fungicides primarily in five ways, which are described in Sections 4.1, 4.2, 4.3, 4.4, 4.5.

Legal Aspects. Before any fungicide can be used in agriculture, it must be registered with the

responsible authorities in the country concerned to ensure that it complies with the necessary health, environmental, and safety requirements (→ Crop Protection, Chap. 6., → Crop Protection, Chap. 7.)

4.1. Seed Treatment

Fungal spores adhering superficially to the surface of seeds (e.g., *Tilletia caries* on wheat) can be controlled easily by nonsystemic fungicides. Others such as *Helminthosporium* spp., which colonize the seed coat in the form of a mycelium, can also be controlled by nonsystemic fungicides, but better control may be obtained with systemic products. Some pathogens establish themselves deeply within the embryonic tissue of the seed (e.g., *Ustilago* spp. on wheat and barley) and can only be controlled effectively with systemic fungicides that can penetrate the seed. Seed lots may be contaminated by dormant structures of fungi (e.g., sclerotia or oospores). Damage to seedlings caused by these fungi, as well as by pathogens living in the soil, can be minimized by appropriate seed treatment.

Systemic fungicides (e.g., metalaxyl used for the control of downy mildew of peas) protect the foliage for several weeks after treatment of the seed.

Fungicides for seed treatment are formulated as dry dusts, wettable powders, or ready-to-use liquids. Dusts are applied directly to the seed but the amount that can be retained on the seed surface may be limited. This may be overcome by mixing the fungicide with the seed during sowing – the so-called planter-box treatment. Wettable powders and liquids are mixed with water and applied as slurries. Liquid formulations are also sprayed onto the seeds with special equipment. Formulations usually contain "stickers" to aid retention on the seed, as well as dyes to indicate that the seed has been treated.

Modern technology employs inert carriers to coat the seed with fungicide; this permits larger amounts of fungicide to be carried on the seed.

4.2. Foliage and Fruit Sprays

The most common method of applying fungicides to foliage and fruit is by a water-based spray solution in which fungicide particles are finely dispersed. This allows uniform coverage of the leaves or fruit. Dust formulations are preferred for some compounds (e.g., sulfur) in certain countries, but they are becoming less popular.

Because nonsystemic fungicides are purely protective, and act by inhibiting spore germination or penetration of the fungus into plant tissue, they must be applied before the arrival of the pathogen. Application must be repeated at short, often weekly, intervals to protect new growth and to replace losses resulting from weathering or wash-off.

Since systemic fungicides enter the plant and are redistributed by translocation, the need for an efficient spray deposit on all susceptible plant surfaces is less critical than for nonsystemic compounds. However, in most cases systemic fungicides are only translocated upward (i.e., acropetally) by means of transpiration; therefore, it is important to ensure good penetration into the lower foliage. Systemic fungicides do not have to be applied as frequently as nonsystemic fungicides because they persist longer within tissues, are less liable to be washed off, and also often protect the new growth. Intervals of 14 – 21 days are often possible, compared with the 7 – 10 days required for nonsystemic compounds. Furthermore, the timing of spraying is not as critical because systemic fungicides can block pathogen development after infection has occurred.

Formulations for use as foliar and fruit sprays include wettable powders, emulsifiable concentrates, suspension concentrates (flowables), and more recently, water-dispersible granules. They all contain agents that ensure uniform dispersion of the active ingredient in the spray mixture and on the plant surface.

4.3. Soil Treatment

The soil-inhabiting fungi responsible for diseases such as seedling damping-off, vascular wilt, and root and basal stem rot are particularly difficult to control. Until recently, all-purpose soil fumigants (e.g., methyl bromide [*74-83-9*]) were the only effective means of chemical control. Fumigants act as general soil sterilants and

kill fungi, insects, and weed seeds. They are phytotoxic and can be used only for a defined period several weeks prior to planting.

Since the mid-1970s, a number of soil-applied fungicides have become available (e.g., metalaxyl, etridiazole, and propamocarb) which permit highly effective control of soil-borne *Phytophthora* and *Pythium* spp.

Soil fungicides are formulated as granules for ease of application, especially in perennial crops, but they are also available in formulations that can be sprayed onto the soil surface. Soil fungicides should be relatively mobile so that they move down to the root zone, but not so mobile that they are leached out of the upper soil layers. Compounds that are applied directly in the furrow during planting to control seedling diseases are placed accurately where needed.

4.4. Trunk Injections

A recent, novel development is the control of *Phytophthora* root rot disease of avocado and citrus trees by means of fungicides injected into the trunk [10]. At present, this technique can be applied only to phosphite fungicides such as fosetyl Al and its degradation product phosphorous acid, which are translocated downward (i.e. basipetally) in appreciable quantities (cf. Chap. 3). Trunk injection is laborious because several holes must be bored in the trunk of each tree. The fungicide solution is then injected by syringe into the trunk, under pressure, over a period of a few hours. If other compounds with similar properties but a different spectrum of activity are discovered, use of this elegant method could be extended to control root diseases of other tree crops.

4.5. Postharvest Treatment

Fungal pathogens are responsible for the majority of postharvest losses in perishable produce such as fruit, vegetables, and starchy root crops with high moisture content. Infection may occur prior to, or during, harvest as well as during storage. Although fungicides that are applied in the field can prevent losses which develop during storage, the term *postharvest fungicides* refers only to compounds that are applied to the harvested crop.

One or two fungi may be initially responsible for disease. However, they are often followed by a number of nonspecific, secondary pathogenic fungi and bacteria which cause extensive tissue breakdown and rotting of the produce. If mechanical injury occurs during harvesting, these secondary microorganisms can establish themselves without the help of primary invaders. Postharvest treatment should not only prevent infection and subsequent spread of disease to healthy produce, but also stop the development of disease after infection has taken place. The chemicals used should, therefore, have penetrating properties (e.g., fumigants or systemic fungicides).

Most postharvest fungicides are used in the fruit export industry to treat crops such as citrus fruit, bananas, and tropical fruit. Compounds such as benzimidazole derivatives, dicarboximides, and triazoles are commonly used for this purpose. The fungicides are generally applied in aqueous solution by dipping, spraying, or brushing, but they are sometimes incorporated into the standard waxes used to treat fruit.

5. Fungicide Resistance

Although fungicides have been used on a large scale for over a century, fungicide resistance has only become an important problem since the early 1970s. The fungicides used until 1970 were protective, nonsystemic substances with a multisite or nonspecific mode of action. The onset of resistance problems coincided with the introduction of systemic compounds having a specific or single-site mode of action. Resistance has, however, not been limited entirely to the systemics; it has also developed in some contact fungicides with site-specific activity, such as the organotin compounds used for the control of *Cercospora beticola* on sugar beet.

Systemic fungicides are especially prone to the development of resistance because of their site-specific mode of action. Phytopathogenic fungi have been able to overcome this specificity because a slight change at the target site results in decreased sensitivity to the fungicide. Such genetic variants may arise spontaneously but occur more frequently in fungi which pro-

duce large numbers of spores and undergo many reproductive cycles during the cropping season.

Resistance to nonsystemic fungicides is rare because they are mostly multisite inhibitors; changes would be required at many sites for resistance to occur.

The mechanisms by which resistance to fungicides can arise are outlined in [8], [11].

The majority of cases in which there has been a reduction in the level of disease control under practical conditions (i.e., field resistance) have occurred when specific systemic fungicides have been used exclusively and often intensively over an extended period of time. Experience has shown that certain types of systemic fungicide are especially prone to sudden, large shifts in sensitivity of part of their target population, which results in complete loss of disease control. This type of resistance development has occurred, for example, in *Venturia inaequalis* (apple scab) treated with benzimidazoles and in *Phytophthora infestans* (potato late blight) treated with phenylamides.

The triazole fungicides belong to a large group of compounds whose mode of action is to inhibit the C-14 demethylation step in ergosterol biosynthesis (for further details, see Section 8.6.1). Their increasing use has been associated with progressive shifts in fungal sensitivity over a period of several years. Field performance was not affected initially, but the levels of control of some diseases [e.g., *Erysiphe graminis* (powdery mildew) of barley] are now lower than when the products were first introduced. The morpholines, which also inhibit ergosterol biosynthesis, have not yet been associated with a resistance problem; they inhibit $\Delta^8 \rightarrow \Delta^7$-isomerization and/or Δ^{14}-reduction.

Measures taken by fungicide manufacturers to manage the resistance problem include (1) supplying "at-risk" compounds solely as prepacked mixtures with nonsystemic fungicides, (2) restricting use to a limited number of sprays or to a well-defined period of the growing season, and (3) discouraging curative use and soil application for the control of air-borne pathogens. Alternate use of fungicides with different modes of action also hinders the development of resistance, and such usage has been actively promoted in many countries both by academic and government departments. These combined measures reduce the selection pressure that is placed on the fungus population.

The activities of the Groupement International des Associations Nationales de Fabricants de Produits Agrochimiques (GIFAP) and the Fungicide Resistance Action Committee (FRAC) [12] have been important in persuading the manufacturers of fungicides that have a common mode of action to agree on common antiresistance strategies. These strategies have, however, tended to erode the unique benefits of systemic fungicides, such as long intervals between spraying, curative activity, low dose rates, and ease of application. Nevertheless, even with the compromises that must be made to manage resistance, the standards of disease control that can be obtained by following these strategies are much higher than those of the 1970s.

6. Nonsystemic (Contact) Fungicides

6.1. Inorganic Compounds

Sulfur (→ Sulfur) was one of the first fungicides used in agriculture and is still widely employed today; it accounts for one-third of inorganic fungicide sales. It is formulated for use as a dust, a colloidal suspension, or a wettable powder. Sulfur's spectrum of activity is narrow and is confined to the powdery mildews, but it also has a side effect on mites. It is used mainly on grapevines but also on orchards, sugar beet, and vegetables. At high temperature, sulfur can be phytotoxic.

Sulfur [*7704-34-9*], S, A_r 32, *mp* 114.5 °C, *bp* 445 °C, *d* 2.06, vapor pressure 527 µPa at 30.4 °C, is a yellow solid which is practically insoluble in water, however, crystalline forms are soluble in carbon disulfide [9, p. 499], [13, pp. 17, 51], [14, p. 123].

Trade Names. Cosan (AgrEvo); Kumulus DF (BASF); Thiovit (Novartis); Microthiol Special (Elf Atochem).

Copper was originally discovered and used in the form of Bordeaux mixture; more than 30 types of copper fungicides are now available (→ Copper Compounds). In terms of market share, copper oxychloride dominates because of its efficacy, coupled with its good crop tolerance; other important types include copper hydroxide and copper oxide. The spectrum of activity is broad, and copper compounds are used on a wide

range of crops including grapevines, coffee, vegetables, fruit, and cocoa. Copper fungicides are relatively persistent on foliage or fruit and are readily redistributed by water, which gives an improved surface cover. Fungitoxicity increases, as does phytotoxicity, with smaller particle size. Although not as active as more modern, organic fungicides, copper compounds are attractive because of their low price and broad spectrum of activity. They are relatively safe and have few official restrictions on their use. Some concern exists, however, regarding the accumulation of copper in soil, particularly on perennial crops.

Copper(II) oxychloride [*1332-40-7*], dicopper chloride trihydroxide, $Cu_2Cl(OH)_3$, M_r 213.6, is a green to blue-green powder which is insoluble in water or organic solvents but soluble in dilute acids and ammonium hydroxide [9, p. 134], [14, p. 121], [15, p. 371].

Copper(II) oxychloride is produced by air oxidation of cuprous salts and scrap copper in sodium chloride solution. Properties and production are described in detail elsewhere (→ Copper Compounds, Chap. 4.3.).

Trade Names. Coprantal; Recop (Novartis); Cupravit (Bayer); Cobax (BASF); Biltox (Rallis); Ossiram (Sipcam); Pasta Caffero (Caffero).

Cuprous oxide [*1317-39-1*], copper(I) oxide, Cu_2O, M_r 143.1, is a yellow to red powder which is insoluble in water and organic solvents but soluble in dilute mineral acid and aqueous solutions of ammonia [9, p. 139], [13, p. 48], [14, p. 121].

Cuprous oxide is produced by reduction of copper(II) salts under alkaline conditions or by electrochemical oxidation of metallic copper.

On exposure to moist air, copper(I) oxide oxidizes to copper(II) compounds. Properties and production are described in detail elsewhere (→ Copper Compounds, Chap. 3.1.).

Trade Names. Copper-Sandoz (Novartis); Copper Nordox (Nordox).

6.2. Organometallic Compounds

Organotin compounds such as triphenyltin hydroxide and triphenyltin acetate act as fungicides. They are used mostly for the control of *Cercospora beticola* on sugar beet and late blight on potatoes. They are phytotoxic if used at high doses and are, therefore, often not used throughout the growing season or, if so, are mixed with dithiocarbamates. Restrictions on their use are enforced in some countries for toxicological or environmental reasons. Organotin compounds exert their fungitoxicity as specific inhibitors of respiration [16, p. 149].

Fentin hydroxide [*76-87-9*], triphenyltin hydroxide, $C_{18}H_{16}OSn$, M_r 367, *mp* 116 – 120 °C, vapor pressure 47 µPa, consists of colorless crystals which are practically insoluble in water but moderately soluble in acetone, dichloromethane, 1,2-dichloroethane, diethyl ether, ethanol, and benzene [9, p. 271], [13, p. 149], [14, p. 130].

Fentin hydroxide is produced by treatment of triphenyltin chloride with potassium hydroxide [17].

Trade Names. Brestan Flow (AgrEvo); Suzu-H (Nihon Nohyaka).

6.3. Dithiocarbamates

Dithiocarbamates are the most widely used group of fungicides, even though mancozeb, the most important compound, was discovered in the 1950. Mancozeb and maneb together account for the bulk of consumption but other products such as zineb, propineb, polyram, and ziram are also commonly used (see also → Dithiocarbamic Acid and Derivatives, Chap. 5.). They have a very broad spectrum of activity and are generally well tolerated by many crops. They are cheap and effective, and constitute the major component of many routine, protective, spray programs. They are being used increasingly as mixtures with systemic fungicides to reduce the risk of resistance and to broaden the spectrum of activity of the systemic compounds.

In the plant, dithiocarbamates are probably converted to their isothiocyanate radicals, which then combine non-specifically with cell constituents such as sulfhydryl-containing enzymes [10, p. 148].

Mancozeb [*8018-01-7*], manganese ethylenebis(dithiocarbamate) (polymeric) complex with zinc salt; the complex contains about 20 % manganese and 2.55 % zinc, flash point 137.8 °C; it is a greyish yellow powder which is insoluble in water and most organic solvents [9, p. 339], [13, p. 66], [14, p. 140].

Mancozeb is produced by reaction of a concentrated solution of zinc sulfate with a suspension of maneb (see below) in water [18].
Trade Names. Dithane M 45 (Rohm & Haas); Manzate (Du Pont); Micane (Sipcam); Vondozeb (Elf Atochem).

Maneb [*12427-38-2*], manganese ethylenebis (dithiocarbamate) (polymeric), $C_4H_6MnN_2S_4$, M_r 265.3, *mp* decomposes on heating without melting, d_4^{25} 1.92, is a yellow crystalline solid which is almost insoluble in water and most organic solvents [9, p. 340], [13, p. 66], [14, p. 139].

Maneb is produced by reaction of disodium ethylenebis(dithiocarbamate) and manganese sulfate [19].
Trade Names. Manzate (Du Pont); Dithane M 22 (Rohm & Haas); Bresten (AgrEvo).

Thiram [*137-26-8*], tetramethylthiuram disulfide, $C_6H_{12}N_2S_4$, M_r 240.4, *mp* 155 – 156 °C, consists of colorless crystals which are practically insoluble in water but soluble in chloroform and acetone [9, p. 534], [13, p. 62], [14, p. 137], [20].

Thiram is produced by careful oxidation of a *N,N*-dimethyl dithiocarbamate salt with hydrogen peroxide, chlorine, or air [21].

Thiram was discovered in 1931 but is still popular today, especially as a broad-spectrum seed treatment for many crops. It is also used as a protective foliar fungicide on vegetables, turf, apples, and bananas, as well as a preplant dip treatment for ornamental bulbs. Crops on which it is used as a soil fungicide include vegetables and cotton.
Trade Names. Pomarsol (Bayer); Aetiram (AgrEvo); Rhodiason (Rhône-Poulenc); Thiram (Uniroyal).

Ferbam [*14486-64-1*], iron tris(dimethyldithiocarbamate), $C_9H_{18}N_3S_6Fe$, M_r 416.5, *mp* > 180 °C (decomp.), is a black powder which is slightly soluble in water and soluble in organic solvents with a high dielectric constant [22, p. 541].

Ferbam is produced by precipitation from an aqueous solution of sodium dimethyldithiocarbamate in the presence of a water-soluble iron salt [23].

Ferbam (announced in 1965) is a foliar fungicide with protective action and secondary action against chlorosis. It is used to control scab on pome fruits, peach leaf curl (*Taphrina deformans*), blue mold on tobacco, and other diseases on other crops.
Trade Name. Ferbam Granuflo (UCB).

Metiram [*9006-42-2*], zinc ammoniate ethylenebis(dithiocarbamate) poly(ethyl-

enethiuram disulfide), $(C_{16}H_{33}N_{11}S_{16}Zn_3)_x$, M_r (1088.7)$_x$, *mp* 156 °C (decomp.), is a yellowish powder which is practically insoluble in water, and most organic solvents but soluble in pyridine (with decomposition) [22, p. 828].

Metiram is produced by addition of a mixture of concentrated sulfuric acid, hydrogen peroxide, and zinc chloride with vigorous stirring to an aqueous solution of *N,N*-tetramethylenedithiocarbamate and sodium ethylenebis(dithiocarbamate) [24].

Metiram (announced in 1958) inactivates fungal proteins by binding to essential thiol groups. It is used to control a wide range of diseases of many crops: scab on pome fruits; shot-hole on stone fruit; rust on currants and plums; downy mildew, red fire disease, and black rot on vines; *Phytophthora* late blight on potatoes and tomatoes; *Septoria* leaf spot on celery and celeriac; and downy mildews on hops and tobacco.
Trade Name. Polyram (BASF).

Propineb [*9016-72-2*], polymeric zinc propylenebis(dithiocarbamate), $(C_5H_8N_2S_4Zn)_x$, M_r (289.8)$_x$, *mp* > 150 °C (decomp.), is a white to yellowish powder which is practically insoluble in all common organic solvents but fairly soluble in a mixture of DMF and dimethyl sulfoxide [22, p. 1032].

Propineb is produced by reaction of an aqueous solution of 1,2-propylenediamine with carbon disulfide in NaOH. The zinc salt is obtained by precipitation with zinc sulfate [25].

Propineb (announced in 1963) is a foliar fungicide used to control downy mildew, black rots, red fire disease, and grey mold on vines; leaf spot diseases on stone fruits; and *Alternaria* and *Phytophthora* blights, downy mildew, *Septoria* leaf spot, and leaf mold in tomatoes.
Trade Name. Antracol (Bayer).

Zineb [*12122-67-7*] polymeric zinc ethylenebis(dithiocarbamate), $(C_4H_6N_2S_4Zn)_x$, M_r (275.8)$_x$, *mp* 157 °C (decomp.), is a light colored powder which is practically insoluble in water and common organic solvents [22, p. 1276.]

Zineb is produced by mixing ethylenebis(dithiocarbamate) with an aqueous zinc sulfate solution [26].

Zineb (announced in 1943) is used to control downy mildews in vines, hops, lettuce, onions, spinach, brassicas, oilseed rape, tobacco and ornamentals; rusts in currants, berry fruits, plums, vegetables, and ornamentals; red fire disease on ornamentals; potato and tomato blights; *Cercospora* on bananas; *Botrytis*; and needle cast in forestry.
Trade Names. Dithane Z-78 (Rohm & Haas); Aphytora (AgrEvo); Amitan (Sipcam).

Ziram [*137-30-4*], zinc bis(dimethyldithiocarbamate), $C_6H_{12}N_2S_4Zn$, M_r 305.8, *mp* 246 °C, is a colorless powder which is practically insoluble in water, slightly soluble in ether and ethanol; and soluble in carbon disulfide and chloroform [22, p. 1277.]

Ziram is produced by precipitation from an aqueous solution of sodium diemthyldithiocarbamate in the presence of a water-soluble zinc salt [27].

Ziram (announced in 1962) is an inhibitor of enzymes containing copper ions or sulfhydryl groups. It is used to control fungicidal diseases in pome fruits, stone fruits, nuts, vines, vegetables, and ornamentals (especially scab in apples and pears), *Monilinia*, *Alternaria*, *Septoria*, peach leaf curl, shot-hole, rusts, black rot, and anthracnose. It is also used as a wildlife repellent.
Trade Names. Cuman (Novartis); Fuclasin (AgrEvo); Pomarsol Z (Bayer).

6.4. *N*-Trihalomethylthio Derivatives (Phthalimides)

Four main phthalimide fungicides were introduced between 1952 and 1961. Captan and folpet are the most important, followed by captafol and ditalimfos; they are used widely as protectant fungicides. Concern has arisen about their safety, especially that of captafol. Restrictions on use have been imposed in some countries, while total bans have been imposed in others.

The fungitoxicity of these compounds is nonspecific and is probably due to enzyme inactivation caused by blocking of sulfhydryl groups.

Captan [*133-06-2*], *N*-(trichloromethylthio)cyclohex-4-ene-1,2-dicarboximide, $C_9H_8Cl_3NO_2S$, M_r 300.6, *mp* 178 °C, vapor pressure < 1.3 mPa at 25 °C, consists of colorless crystals which are practically insoluble in water but partially soluble in acetone, chloroform, cyclohexanone, and xylene [9, p. 87], [13, p. 108], [14, p. 190].

Captan is produced by reaction of 1,2,3,6-tetrahydrophthalimide with trichloromethanesulfenyl chloride (perchloromethylmercaptan) in the presence of sodium hydroxide [28].

Captan is used as a foliar fungicide for the control of scab (*Venturia inaequalis*) of apples and pears, as well for other diseases of fruit, vegetable, and ornamental crops. It is also used as a seed or planter-box treatment, as a preplant soil treatment, or as a postharvest fungicide.

Trade Names. Phytocape (Bayer); Captof (Rallis).

Folpet [*133-07-3*], *N*-(trichloromethylthio)-phthalimide, $C_9H_4Cl_3NO_2S$, M_r 296.6, *mp* 177 – 180 °C (decomp.), consists of white crystals which are practically insoluble in water and slightly soluble in organic solvents [13, p. 109], [14, p. 191], [29, p. 518].

Folpet is produced by reaction of the potassium salt of phthalimide with trichloromethanesulfenyl chloride in organic solvents [28].

Folpet is used as a foliar fungicide on grapevines, fruit trees, and vegetables, and is active against a wide range of diseases including downy mildew, leaf spot, powdery mildew, and rust as well as black rot and dead arm of grapes.

Trade Name. Folpan (Makhteshim-Agan, Philagro).

Dichlofluanid [*1085-98-9*], *N*-dichlorofluoromethylthio-*N′*,*N′*-dimethyl-*N*-phenylsulfamide, $C_9H_{11}Cl_2FN_2O_2S_2$, M_r 333.2, *mp* 105 – 106 °C, vapor pressure 133 µPa at 20 °C, is a colorless powder which is practically insoluble in water, slightly soluble in methanol and xylene, and soluble in dichloromethane [9, p. 175], [13, p. 95], [14, p. 193].

Dichlofluanid is produced by reaction of *N′*,*N′*-dimethyl-*N*-phenylsulfamide with dichlorofluoromethanesulfenyl chloride in the presence of a base [30].

Dichlofluanid (announced in 1965) is used as a preventative foliar fungicide against *Botrytis* and downy mildew on grapevines. It has largely been replaced by more effective compounds (e.g., dicarboximides), but interest has been renewed recently because of resistance to dicarboximides.

Trade Names. Euparen, Elvaron (Bayer).

Captafol [*2425-06-1*], *N*-(1,1,2,2-tetrachloroethylthio)cyclohex-4-ene-1,2-dicarboximide, $C_{10}H_9Cl_4NO_2S$, M_r 349.1, *mp* 160 – 161 °C, is a light tan powder which is practically insoluble in water and slightly soluble in most organic solvents [22, p. 175].

Captafol is produced by reaction of the sodium salt of tetrahydrophthalimide in benzene with tetrachloroethylsulfenyl chloride [31].

Captafol (announced in 1962) acts by inhibiting germination of spores. It is used to control scab on pome fruits, shot-hole in some stone fruit; peach leaf curl, downy mildew and black rot of vines; *Alternaria* and mildew of carrots; *Septoria* of wheat; *Rhynchosporium* of barley; and various diseases of vegetables and fruits.
Trade Names. Difoltan, Foltaf (Rallis).

Tolylfluanid [*731-27-1*], *N*-dichlorofluoromethylthio-*N′*,*N′*-dimethyl-*N*-*p*-tolylsulfamide, $C_{10}H_{13}Cl_2FN_2O_2S_2$, M_r 347.2, *mp* 93 °C, is a colorless to pale yellow powder which is practically insoluble in water, and soluble in organic solvents [22, p. 1208.]

Tolylfluanid is produced by reaction of the potassium salt of *N′*,*N′*-dimethyl-*N*-*p*-tolylsulfamide with dichlorofluoromethylthiochloride in xylene with heating [32].

Tolylfluanid (announced in 1967) is used in deciduous fruit crops to control *Venturia* spp. and *Podosphaera leucotricha*. It is also used against storage diseases; in grapes against *Uncinula necator*, *Plasmopara viticola*, and *Botrytis cinerea*; and in vegetables against *B. cinerea*, *Peronospora* spp., and powdery mildew.
Trade Names. Elvaron M, Euparen M (Bayer).

6.5. Dicarboximides

The dicarboximide fungicides include iprodione, procymidone, vinclozolin, and metomeclan, which are all *N*-3,5-dichlorophenyl derivatives of cyclic imides. They are used to control diseases caused by the taxonomically related genera *Sclerotinia, Monilinia*, and *Botrytis*. They are generally considered nonsystemic, protectant fungicides, but evidence exists for systemic transport in some plants. They share a common mode of action with a probable primary effect on nuclei, but they may also affect the cytoplasmic membrane and/or the cell wall [16, pp. 207 – 237]. Resistance problems have occurred in several field crops, notably in *Botrytis* spp. [33, p. 101].

Iprodione [*36734-19-7*], 3-(3,5-dichlorophenyl)-*N*-isopropyl-2,4-dioxoimidazolidine-1-carboxamide, $C_{13}H_{13}Cl_2N_3O_3$, M_r 330.2, *mp* 136 °C, vapor pressure 133 µPa at 20 °C, consists of colorless crystals which are practically insoluble in water, slightly soluble in ethanol and methanol, and soluble in many organic solvents such as acetone or dichloromethane [9, p. 322], [14, p. 209].

Iprodione is produced by reaction of 3,5-dichlorophenyl isocyanate with glycine, followed by ring closure to give the hydantoin, then treatment with isopropyl isocyanate [34].

Iprodione (announced in 1970) has both preventative and curative properties. It is used against turf grass diseases, *Alternaria* diseases of apples, pears, and oilseed rape, as well as *Botrytis, Monilinia,* and *Sclerotinia* diseases of grapevines, fruit, and vegetables.
Trade Names. Rovral, Kidan, Verisan (Rhône-Poulenc).

Vinclozolin [*50471-44-8*], (*RS*)-3-(3,5-dichlorophenyl)-5-methyl-5-vinyl-1,3-oxazolidine-2,4-dione, $C_{12}H_9Cl_2NO_3$, M_r 286.1, *mp* 108 °C, vapor pressure < 10 mPa at 20 °C, consists of colorless crystals which are slightly soluble in water but more soluble in acetone, benzene, chloroform, and ethyl acetate [9, p. 558], [14, p. 217].

Vinclozolin is produced by reaction of 3,5-dichlorophenyl isocyanate with an alkyl ester of

2-hydroxy-2-vinylpropionic acid; ring closure is achieved at elevated temperature [35].

Vinclozolin (announced in 1973) has a similar spectrum of activity to iprodione and is used to control specific diseases of rape, grapevines, apples, and pears. Although it is a nonsystemic fungicide, it also has a local systemic effect and displays curative properties up to 36 h after infection.

Trade Names. Ronilan (BASF); Flotilla (Barclay).

Procymidone [*32809-16-8*], *N*-(3,5-dichlorophenyl)-1,2-dimethylcyclopropane-1,2-dicarboximide, $C_{13}H_{11}Cl_2NO_2$, M_r 284.1, *mp* 164–166 °C, vapor pressure 10.5 mPa at 20 °C, is a light-brown solid which is practically insoluble in water but slightly soluble in methanol or xylene [9, p. 453].

Procymidone is produced by reaction of 1,2-dimethylcyclopropanedicarboxylic anhydride and 3,5-dichloroaniline; the resulting monoamide is then cyclized with acetic anhydride and a catalytic amount of anhydrous sodium acetate at 100 °C [36].

Procymidone (announced in 1976) has a similar spectrum of activity to vinclozolin and iprodione. It has systemic properties and is used as a foliar fungicide with protective and eradicative properties.

Trade Names. Sumisclex, Sumilex (Sumitomo).

Chlozolinate [*72391-46-9*], ethyl(±)-3-(3,5-dichlorophenyl)-5-methyl-2,4-dioxo-1,3-oxazolidine-5-carboxylate, $C_{13}H_{11}Cl_2NO_5$, M_r 332.1, *mp* 112.6 °C, is an almost colorless powder which is practically insoluble in water, and soluble in most organic solvents [22, p. 244].

Chlozolinate is produced by reaction of 3,5-dichlorophenylisocyanate with hydroxymethyl diethylmalonate in benzene followed by the addition of triethylamine [37].

Chlozolinate (announced in 1980) is used to control *Botrytis* spp., *Sclerotina* spp., and *Monilinia* spp. in ornamentals, vegetables, vines, pome fruits, stone fruits, sunflowers, and strawberries.

Trade Name. Serinal (Isagro).

6.6. Miscellaneous Organic Compounds

Quintozene [*82-68-8*], pentachloronitrobenzene, $C_6Cl_5NO_2$, M_r 295.3, *mp* 146 °C, d_4^{25} 1.718, vapor pressure 1.8 Pa at 25 °C, consists of colorless crystals which are practically insoluble in water but soluble in benzene and chloroform [9, p. 484], [13, p. 73], [14, p. 154].

Quintozene is prepared by chlorination of nitrobenzene at 60–70 °C in chlorosulfuric acid, with iodine as a catalyst [38].

Quintozene was discovered in the 1930s but is still used frequently as a soil fungicide or seed treatment. It is particularly effective for the control of soil-borne *Rhizoctonia* and *Sclerotinia* spp. Very high rates are required when it is applied to the soil during or prior to planting.

Trade Names. Brassicol (AgrEvo); Terrachlor, Folosan (Uniroyal); Kobutol (Hokko).

Dodine [*2439-10-3*], 1-dodecylguanidinium acetate, $C_{15}H_{33}N_3O_2$, M_r 287.4, *mp* 136 °C, consists of colorless crystals which are practically insoluble in water and most organic solvents but soluble in hot alcohol and hot water [9, p. 229], [13, p. 70], [14, p. 145], [15, p. 374].

Dodine is produced by reaction of 1-dodecylamine with cyanamide and acetic acid [39].

Dodine (announced in 1959) has preventative as well as eradicative properties because of its

local systemic activity. It is used mainly for control of apple scab but also for fruit rot and leaf spot diseases of deciduous fruit and nuts.
Trade Names. Cyprex, Venturol, Melprex (Cyanamid, Rhône-Poulenc); Dodene (Sipcam).

Dithianon [*3347-22-6*], 5,10-dihydro-5,10-dioxonaphtho-[2,3-*b*]-1,4-dithiin-2,3-dicarbonitrile, $C_{14}H_4N_2O_2S_2$, M_r 296.3, *mp* 225 °C, vapor pressure 66 µPa at 25 °C, consists of brown crystals which are practically insoluble in water and only slightly soluble in organic solvents [9, p. 225], [13, p. 105].

Dithianon is produced by reaction of hydrogen cyanide with carbon disulfide in dimethylformamide to yield dimercaptomaleic acid dinitrile; this intermediate is then treated with 2,3-dichloronaphthoquinone [40].

Dithianon (announced in 1963) is a protective contact fungicide with a broad spectrum of activity against, for example, leaf and fruit spot diseases, downy mildew, late blight, anthracnose, and rust. It is relatively expensive and is used on crops (e.g., deciduous fruit trees and coffee) only when it produces significant benefits that are not obtained with cheaper contact fungicides such as dithiocarbamates.
Trade Names. Actuan, Delen (Cyanamid); Cluster (Barclay).

Chlorothalonil [*1897-45-6*], tetrachloroisophthalonitrile, $C_8Cl_4N_2$, M_r 265.9, *mp* 250–251 °C, *bp* 350 °C, vapor pressure 1.3 Pa at 40 °C, consists of colorless crystals which are practically insoluble in water but slightly soluble in organic solvents such as acetone, cyclohexanone, and xylene [9, p. 120], [13, p. 91], [14, p. 163].

Chlorothalonil is produced by reaction of tetrachloroisophthalyl chloride with ammonia to give the diamide which, on treatment with phosphorus oxychloride, yields the dinitrile [41].

Chlorothalonil (announced in 1964) has a broad spectrum of activity and is used as a preventative foliar fungicide on a wide range of crops including vegetables, turf, top fruit, coffee, groundnuts, and cereals. It is relatively expensive and is usually used on more valuable cultures.
Trade Names. Bravo (ISK Biosciences); Daconil (SDS Biotech, Zeneca, ISK Biosciences).

Etridiazole [*2593-15-9*], 5-ethoxy-3-trichloromethyl-1,2,4-thiadiazole, $C_5H_5Cl_3N_2OS$, M_r 247.5, *mp* 20 °C, *bp* 95 °C at 0.13 kPa, vapor pressure 13 mPa at room temperature, is a yellow liquid with a persistent odor; it is practically insoluble in water but soluble in many organic solvents [9, p. 252], [14, p. 219], [15, p. 397].

Etridiazole is produced by reaction of trichloroacetamidine hydrochloride with trichloromethanesulfenyl chloride and then with sodium hydroxide in ethanol [42].

Etridiazole (announced in 1969) is a soil fungicide with preventative and curative properties. It is effective against *Phytophthora* and *Pythium* spp. and is used on turf, ornamentals, vegetables, avocados, and other crops. It can be applied to the soil surface or mixed with the soil prior to planting.
Trade Name. Terrazole (Uniroyal).

Phthalide [*27355-22-2*], 4,5,6,7-tetrachlorophthalide, $C_8H_2Cl_4O_2$, M_r 271.9, *mp* 209–210 °C, consists of colorless crystals which are practically insoluble in water and only slightly soluble in organic solvents [9, p. 517], [14, p. 197].

Phthalide is produced by treatment of 1,2-bis(dichloromethyl)-3,4,5,6-tetrachlorobenzene with 75 % sulfuric acid [43].

Phthalide (announced in 1971) is a foliar fungicide with preventative properties for the control of blast in rice.
Trade Names. Rabcide (Kureha); Kasurabcide (Hokko).

Toclofos-methyl [*57018-04-9*], *O*-2,6-dichloro-*p*-tolyl-*O,O*-dimethyl phosphorothioate (or thiophosphate), $C_9H_{11}Cl_2O_3PS$, M_r 301.1, *mp* 78 – 80 °C, vapor pressure 57 mPa at 20 °C, consists of colorless crystals which are practically insoluble in water but soluble in acetone, cyclohexanone, and xylene [4, p. 536].

Toclofos-methyl is produced by reaction of 2,6-dichloro-*p*-cresol with (*O,O*-dimethyl) chlorothiophosphate in the presence of a base [44].

Toclofos-methyl (announced in 1973) is a contact fungicide for the control of soil-borne diseases caused by *Rhizoctonia solani* and by *Sclerotium* and *Typhula* spp. on potatoes, sugar beet, cotton, groundnuts, vegetables, cereals, and turf. It is used as a seed treatment and a soil fungicide.
Trade Name. Rizolex (Sumitomo, Du Pont).

Cymoxanil [*57966-95-7*], 1-(2-cyano-2-methoxyiminoacetyl)-3-ethylurea, $C_7H_{10}N_4O_3$, M_r 198.2, *mp* 160 – 161 °C, d^{25} 1.31, vapor pressure 80 µPa at 25 °C, is a colorless crystalline solid which is slightly soluble in water and benzene but soluble in acetone, chloroform, and dimethylformamide [9, p. 148], [14, p. 146], [15, p. 405].

Cymoxanil is produced by condensation of cyanoacetic acid with ethylurea in the presence of acetic anhydride; the resulting 2-cyano-*N*-ethylcarbamoyl acetamide is converted to the hydroximino derivative which is methylated with dimethyl sulfate [45].

Cymoxanil (announced in 1977) has local penetrating properties and a curative mode of action. Persistence in the plant is relatively short (3 – 5 days), especially at higher temperatures. Therefore, it is used only in mixtures with contact fungicides to which it gives a "kick-back" (curative) action. It is used against downy mildew of grapes and late blight of potatoes.
Trade Names. Curzate (Du Pont); Pulsan (Novartis).

Pencycuron [*66063-05-6*], 1-(4-chlorobenzyl)-1-cyclopentyl-3-phenylurea, $C_{19}H_{21}ClN_2O$, M_r 328.8, vapor pressure < 1 mPa at 20 °, consists of colorless crystals which are practically insoluble in water but soluble in dichloromethane [9, p. 422].

Pencycuron is produced by reaction of *N*-(4-chlorobenzyl)cyclopentylamine with phenyl isocyanate [46].

Pencycuron (announced in 1981) is used for the control of diseases caused by *Rhizoctonia solani,* such as rice sheath blight, black scurf of potatoes, and damping-off of ornamentals.
Trade Name. Monceren (Bayer).

Fenpiclonil [*74738-17-3*], 4-(2,3-dichlorophenyl)pyrrole-3-carbonitrile, $C_{11}H_6Cl_2N_2$, M_r 237.1, *mp* 153 °C, vapor pressure 42 µPa at 20 °C, consists of colorless crystals which are practically insoluble in water, slightly soluble in methanol and dichloromethane, and soluble in acetone and cyclohexanone [47, p. 65].

Fenpiclonil can be produced by reaction of either 2-(2,3-dichlorophenyl)acrylonitrile or 1-cyano-2-(2,3-dichlorophenyl)ethyl cinnamate with *p*-toluenesulfonylmethyl isocyanate in dimethoxyethane in the presence of a base such as sodium hydride or sodium methoxide [48].

Fenpiclonil was announced in 1988 as a seed treatment fungicide. On cereals it has been introduced for the control of *Gerlachia nivalis (Fusarium nivale)* and *Tilletia caries* as well as seed-borne *Septoria nodorum.* In combination with imazalil it allows control of *Pyrenophora graminea* and *Pyrenophora teres* in barley. It is also being developed for use on noncereal crops where it shows activity against a broad spectrum of Ascomycetes, Deuteromycetes and Basidiomycetes pathogens.
Trade Names. Beret, Gambit (Novartis).

Biphenyl [*92-52-4*], $C_{12}H_{10}$, M_r154.2, *mp* 69 – 71 °C, consists of colorless crystals which are practically insoluble in water but readily soluble in most organic solvents [22, p. 128.]

Biphenyl is produced by reaction of phenylmagnesium bromide with 1,4-dimethyl-2,3-dibromobutane in an inert solvent [49].

Biphenyl (announced in 1944) is a fungistat that inhibits sporulation. It is used to impregnate citrus fruit wraps to prevent fungal attack.

2-Phenylphenol [*90-43-7*], biphenyl-2-ol, $C_{12}H_{10}O$, M_r 170.2, *mp* 57 °C, is a colorless crystalline solid which is slightly soluble in water and soluble in most organic solvents [22, p. 955.]

2-Phenylphenol is produced by heating 6-phenyl-2,5-hexadienoic acid in a mixture of acetic hydride, acetic acid, and sodium acetate [50].

2-Phenylphenol (announced in 1936) is used as a desinfectant fungicide in post-harvest control of storage dieseases of apples, citrus fruits, tomatoes, cucumbers, and capsicums.

Diphenylamine [*122-39-4*], $C_{12}H_{11}N$, M_r 169.2, *mp* 53 – 54 °C, consists of colorless crystals which are sparingly soluble in water but readily soluble in organic solvents [22, p. 435].

Diphenylamine is produced by heating a mixture of aniline hydrochloride and aniline, and extraction of the product with hydrchloric acid, followed by distillation of the extract [51].

Diphenylamine (announced in 1940) is used as a post-harvest fungicide protectant and scald inhibitor for pome fruit.
Trade Names. Coraza (Productos OSA); No Scald (Elf Atochem).

***sec*-Butylamine** [*13952-84-6*], (*R,S*)-*sec*-butylamine, $C_4H_{11}N$, M_r 73.1, *bp* 63 °C, is a colorless liquid which is miscible with water and with most organic solvents [22, p. 169].

sec-Butylamine is produced by is produced by heating a mixture of *sec*-butylbromide, potassium isocyanate, and ethanol in DMF, followed by hydrolysis of the resulting urethane [52].

sec-Butylamine (announced in 1962) is used in fungicidal fumigation of seed and ware potatoes for control of skin spot and gangrene; and against citrus blue, green molds and stem rot of oranges.
Trade Name. Deccotane (Elf Atochem).

Chinomethionat [*2439-01-2*], *S,S*-(6-methylquinoxaline-2,3-diyl) dithiocarbamate, $C_{10}H_6N_2OS_2$, M_r 234.3, *mp* 170 °C, consists of yellow crystals which are sparingly soluble in water but soluble in cyclohexanone and DMF [22, p. 198].

Chinomethionat is produced by reaction of 7-methyl-2,3-quinoxaline thiol with carbonyl chloride [53].

Chinomethionat (announced in 1960) is used to control powdery mildews and spider mites on fruit, ornamentals, cucurbits, cotton, coffee, tea, tobacco, walnuts, vegetables, and glasshouse crops.
Trade Name. Morestan (Bayer).

Dichlorophen [*97-23-4*], 4,4′-dichloro-2,2′-methylenediphenol, $C_{13}H_{10}Cl_2O_2$, M_r 269.1,

mp 177 – 178 °C, consists of colorless crystals which are sparingly soluble in water but soluble in acetone and ethanol [22, p. 364].

Dichlorophen is produced by gradually adding an aqueous solution of formaldehyde to a mixture of *p*-chlorophenol and sulfuric acid in methanol [54].

Dichlorophen (announced in 1946) is used to control moss, red thread, *Fusarium* patch, and dollar spot in turf; and against moss on paths, walls, roofs, and noncrop land.
Trade Name. Super Mosstox (Rhône-Poulenc).

Diclomezine [*62865-36-5*], 6-(3,5-dichloro-4-methylphenyl)pyridazin-3(2*H*)-one, $C_{11}H_8Cl_2N_2O$, M_r 255.1, *mp* 250.5 – 253.5 °C, consists of colorless crystals which are sparingly soluble in water and fairly soluble in methanol and acetone [22, p. 377].

Diclomezine is produced by the Friedel – Crafts reaction of toluene with succinic anhydride, followed by chlorination to give 4-methyl-3,5-dichlorobenzoylpropionic acid, which is further chlorinated to yield 4-methyl-3,5-dichlorobenzoyl-2-chloropropionic acid. The latter is then treated with hydrazine [55].

Dichlomezine (announced in 1988) inhibits septum formation and mycelial growth. It is used to control *Rhizoctonia* and *Sclerotinium* spp. in rice and white mold and twig rot on peanuts.
Trade Name. Monguard (Sankyo).

Dicloran [*99-30-9*], 2,6-dichloro-4-nitroaniline, $C_6H_4Cl_2N_2O_2$, M_r 207.0, *mp* 195 °C, is a yellow crystalline solid which is slightly soluble in water and soluble in acetone, benzene, chloroform, cyclohexane, and dioxan [22, p. 378].

Dicloran is produced by chlorination of 4-nitro-*o*-anilinesulfonic acid to form the monochloro product, which is further chlorinated to yield dichloran [56].

Dicloran (announced in 1960) interferes with the transfer of ribonucleic acid complex to the ribosome and inhibits protein synthesis without affecting respiration. It is used to control *Botrytis*, *Monilinia*, *Rhizopus*, *Sclerotina*, and *Sclerotium* spp. on stone fruits, berry fruits, vines, rhubarb, potatoes, ornamentals, and lettuce.
Trade Names. Allisan, Botran (Gowen).

Fenfuram [*24691-80-3*], 2-methyl-3-furanilide, $C_{12}H_{11}NO_2$, M_r 201.2, *mp* 109 – 110 °C, is a cream-colored solid which is slightly soluble in water and soluble in acetone, cyclohexane, and methanol [22, p. 512].

Fenfuram is produced by heating 2-methyl-4,5-dihydrofuran-3-carboxylic acid with sulfonyl chloride, followed by reaction with aniline [57].

Fenfuram (announced in 1970) is used as a seed treatment to control bunts and smuts (*Tilletia* and *Ustilago* spp.) in cereals.
Trade Name. Pano-ram (Rhône-Poulenc).

Ferimzone [*89269-64-7*], (*Z*)-2′-methylacetophenone-4,6-dimethylpyrimidin-2-yl hydrazone, $C_{15}H_{18}N_4$, M_r 254.3, *mp* 175 – 176 °C, consists of colorless crystals which are sparingly soluble in water but readily soluble in ethanol, ethyl acetate, chloroform, xylene, and acetonitrile [22, p. 543.]

Ferimzone is produced by condensation of 2-methylacetophenone with 4,6-dimethyl-2-hydrazinopyrimidine [58].

Ferimzone (announced in 1984) is used to control *Helminthosporium oryzae*, *Cercospora oryzae*, and *Pyricularia oryzae* in rice.
Trade Name. Blasin (Takeda).

Fludioxonil [*131341-86-1*], 4-(2,2-difluoro-1,3-benzodioxol-4-yl)pyrrole-3-carbonitrile, $C_{12}H_6F_2N_2O_2$, M_r 248.2, *mp* 199.8 °C, consists of colorless crystals which are sparingly soluble in water, and hexane, moderately soluble in toluene, *n*-octanol and ethanol, and readily soluble in acetone [22, p. 566.]

Fludioxonil is produced by reactionof 4-amino-2,2-difluorobenzodioxide in hydrochloric acid-containing acetic acid with sodium nitrite at 0 °C, followed by addition of ethylenenitrile, methyl ethyl ketone, and a solution of copper(I) chloride in hydrochloric acid. The product is extracted with dichloromethane and the thus-obtained solution refluxed in the presence of triethylamine to give 2,3-(difluoromethylenedioxy)cinnamic acid nitrile, which is treated with *p*-toluenesulfonylmethylisocyanide and potassium *tert*-butoxide in THF [59].

Fludioxonil (announced in 1991) is used as seed treatment for control of *Gibberella* in rice and to control *Fusarium*, *Rhizoctonia*, *Tilletia*, *Helminthosporium*, and *Septoria*, in cereal and noncereal crops.
Trade Names. Celest, Maxim (Novartis).

Fluoroimide [*41205-21-4*], 2,3-dichloro-*N*-4-fluorophenylmaleimide, $C_{10}H_4Cl_2FNO_2$, M_r 260.1, *mp* 140 – 214 °C, consists of yellow crystals which are sparingly soluble in water and soluble in methanol and acetone [22, p. 582.]

Fluoroimide is produced by reaction of 2,3-dichloromaleic acid in aqueous solution with *p*-fluoroaniline [60].

Fluoroimide (announced in 1978) inhibits sulfhydryl-containing enzymes in the pathogen. It controls *Monilinia mali* and *Mycosphaerella pomi* in apples and *Doaporthe citri* and *Elsinoe fawcetti* in citrus fruits.
Trade Name. Sparticide (Mitsubishi Chemical).

Flusulfamide [*106917-52-6*], 2',4-dichloro-α,α ,α-trifluoro-4′-nitro-*m*-toluenesulfonamide, $C_{13}H_7Cl_2F_3N_2O_4S$, M_r 415.2, *mp* 169-171 °C, consists of light yellow crystals which are sparingly soluble in water, fairly soluble in methanol, acetone, and THF, and readily soluble in xylene [22, p. 605].

Flusulfamide is produced by reaction of 2-chloro-4-nitroaniline with 3-chloro-4-trifluoromethylphenylsulfenyl chloride in 1,3-dimethyl-2-imidazolidone in the presence of sodium hydride [61].

Flusulfamide (announced in 1987) is used as a soil treatment for control of *Plasmodiophora brassica* in brassica and *Polymyxa betae* in suger beet.
Trade Name. Nebijn (Mitsui Toatsu).

Mepanipyrim [*110235-47-7*], *N*-(4-methyl-6-prop-1-ynylpyrimidin-2-yl)aniline, $C_{14}H_{13}N_3$, M_r 223.3, *mp* 132.8 °C, is a colorless crystalline solid which is slightly soluble in water and fairly soluble in most organic solvents [22, p. 784].

Mepanipyrim is produced by reaction of 4-methyl-6-prop-1-ynylpyrimidine with a mixture of NaOH and formanilide in THF at room tem-

perature, followed by the addition of 4N HCl and refluxing the mixture [62].

Mepanipyrim (announced in 1990) inhibits secretion of pathogen proteins such as the cell-wall degrading enzyme pectinase. It is used to control gray mold on vines, strawberries, tomatoes and cucumbers; scab on apples and pears; and brown rot on peaches.
Trade Name. Frupica (Kumiai).

Nitrothal-isopropyl [*10552-74-6*], diisopropyl 5-nitroisophthalate, $C_{14}H_{17}NO_6$, M_r 295.3, *mp* 65 °C, consists of yellow crystals which are sparingly soluble in water and soluble in acetone, benzene, chloroform, and ethyl acetate [22, p. 884].

Nitrothal-isopropyl is produced by reaction of 5-nitroisophthaloyl chloride with isopropanol in an inert solvent [63].

Nitrothal-isopropyl (announced in 1973) is used in combination with other fungicides for control of powdery mildews on apples, vines, hops, vegetables, and ornamentals and scab on apples.
Trade Names. Kumulan, Pallined (BASF).

Oxycarboxin [*5259-88-1*], 5,6-dihydro-2-methyl-1,4-oxathi-ine-3-carboxanilide 4,4-dioxide, $C_{12}H_{13}NO_4S$, M_r 267.3, *mp* 119.5 – 122.5 °C, consists of colorless crystals which are moderately soluble in water, and fairly soluble in acetone, DMF, ethanol, and methanol [22, p. 916].

Oxycarboxin is produced by oxidation of oxathiin, which is prepared by reaction of acetoacetanilide with sulfonyl chloride, followed by treatment with a potassium hydroxide solution and then with 2-mercaptoethanol [64].

Oxycarboxin (announced in 1966) is used to control rust diseases on ornamentals, cereals, and nursery trees; and fairy rings on turf.
Trade Names. Plantvax (Uniroyal); Carbojet (Maughet).

Triazoxide [*72459-58-6*], 7-chloro-3-imidazol-1-yl-1,2,4-benzotriazine 1-oxide, $C_{10}H_6ClN_5O$, M_r 247.7, *mp* 182 °C, consists of light yellow crystals which are sparingly soluble in water and moderately soluble in hexane, isopropanol, toluene, and dichloromethane [22, p. 1228].

Triazoxide is produced by reaction of 3,7-dichloro-1,2,4-benzotriazine 1-oxide with imidazole in pyridine [65].

Triazoxide (announced in 1980) is used as a seed dressing for control of seed-borne *Pyrenophora graminea* and *Pyrenophora teres* in barley. Only used in combination with other fungicides.
Trade Names. Brio, Gaucho Orge, Raxil S (Bayer).

7. Fungicidal Antibiotics

The antibiotics dealt with in this chapter are described in more detail elsewhere (→ Antibiotics).

The earliest antibiotic used in agriculture, griseofulvin, was developed in England in 1939 by the British Ministry of Agriculture. It is a systemic fungicide that acts against *Botrytis* spp. and powdery mildew diseases but has only been used to a very limited extent on vegetable crops. The next important discovery was that of cycloheximide in 1946 by The Upjohn Company. Although its spectrum of activity was broader than that of griseofulvin, practical use was limited by its phytotoxicity. The success of antibiotics in human medicine stimulated a more intensive search for agricultural fungicides in the 1950s, especially for compounds that could be used to control rice diseases. This led in 1959 to the discovery of blasticidin S, a compound with

nonsystemic, preventative properties which was used for the control of rice blast. This compound was superseded by kasugamycin (announced in 1965). Like blasticidin, kasugamycin acts by inhibiting protein synthesis and is used to control rice blast. It, in turn, has largely been replaced by more modern compounds but remains important in some countries because of its low price. Resistance to kasugamycin has been found under field conditions, but resistant strains are somewhat less biologically fit than sensitive ones [33, p. 207].

The limited number of antibiotics developed to control plant pathogens is due partially to their high cost and to the incompatibility of using them in both medicine and agriculture. In some countries, however, streptomycin is used for both purposes. The most successful antibiotics for agricultural use are the polyoxins and validamycin.

Polyoxin B [*19396-06-6*], $C_{17}H_{25}N_5O_{13}$, M_r 507.4, *mp* 160°C, is an amorphous powder which is soluble in water but insoluble in most organic solvents [9, p. 450], [14, p. 230], [15, p. 226], [66]. See also → Antibiotics.

Polyoxin B is produced by fermentation of *Streptomyces cacaoi* var. *asoensis* [67]. About 15 structurally related polyoxins are known, with polyoxins B and D having the greatest commercial importance.

Polyoxin B, a streptomycin antibiotic, was introduced in 1965 as a foliar fungicide and is somewhat systemic in activity. It is used to control black spot of Japanese pear caused by *Alternaria kikuchiana* and also to control rice blast. Four years after it was first used on pears, poor field performance occurred as a result of resistance developed. However, the proportion of fungicide-resistant strains dropped when use was discontinued [16, p. 105]. Polyoxins act by inhibiting chitin synthesis.

Trade Name. Polyoxin AL (Kaken, Kumiai, Nihon, Nohyaku, Hokko).

Validamycin [*37248-47-8*], $C_{20}H_{35}NO_{13}$, M_r 497.5, decomposes over a wide temperature range around 130 °C, $[\alpha]_D^{24}$ +110° (water); it is a colorless powder which is soluble in water, dimethylformamide, dimethyl sulfoxide, and methanol [9, p. 554], [14, p. 228], [15, p. 231]. See also → Antibiotics.

Validamycin is produced by fermentation of *Streptomyces hygroscopicus* var. *limoneus* [68]; for structural elucidation see [69].

Validamycin (announced in 1970) is a nonsystemic antibiotic with fungicidal properties against Basidiomycetes. It is used widely against *Rhizoctonia solani* of the anastamosis group I, which causes sheath blight of rice. In addition, it is used in some countries to control black scurf of potatoes, caused by *R. solani* anastamosis group IV. Validamycin has a short half-life in the soil (< 4 h) and is, therefore, environmentally favorable. It is sold in dust and liquid formulations and is more effective as a curative than as a protective treatment. The mode of action may be direct by preventing the pathogen from penetrating the host, or indirect by slowing pathogen growth so that host defense mechanisms can be mobilized [16, p. 118]. Resistance to validamycin has not appeared in practice.

Trade Names. Validacin (Takeda); Solacol (AgrEvo); Mycin (Sanonda).

8. Systemic Fungicides

8.1. Organophosphates

Iprobenfos [*26087-47-8*], *S*-benzyl-*O,O*-diisopropyl phosphorothioate, (thiophosphate), $C_{13}H_{21}O_3PS$, M_r 288.3, *bp* 126 °C at 5.3 Pa, is a yellow oil which is slightly soluble in water but soluble in most organic solvents [9, p. 44], [14, p. 232].

Iprobenfos is produced by reaction of the ammonium or alkali salt of diisopropyl thiophosphate and benzyl chloride [70].

Iprobenfos (announced in 1964) is a systemic fungicide with protective and eradicative properties. It is used against rice diseases and is applied to the foliage or into paddy water. Resistance in *Pyricularia oryzae* has been reported from experimental fields after intensive use over a number of years [33, p. 133].

Iprobenfos inhibits the biosynthesis of phosphatidylcholine, an important constituent of the cell membrane [33, p. 35].

Trade Names. Kitazin P, Kitazin (Kumiai).

Edifenphos [*17109-49-8*], *O*-ethyl-*S,S*-diphenyl phosphorodithioate, (dithiophosphate), $C_{14}H_{15}O_2PS_2$, M_r 310.4, *bp* 154 °C at 1.33 Pa, is a yellow to light-brown liquid which is practically insoluble in water but readily soluble in acetone, xylene, and methanol [9, p. 231], [13, p. 132], [14, p. 234].

Edifenphos is produced by reaction of *O*-ethylphosphoryl dichloride with thiophenol in the presence of a base [71].

Edifenphos (announced in 1967) has preventative and eradicative properties. It is used as a foliar fungicide on rice for the control of blast, sheath blight, and stem rot. Its mode of action is to inhibit lipid biosynthesis [33, p. 35].

Trade Names. Hinosan, Hinorebcide (Bayer).

Pyrazophos [*13457-18-6*], ethyl 2-diethoxythiophosphoryloxy-5-methylpyrazolo[1,5-α]-pyrimidine-6-carboxylate, $C_{14}H_{20}N_3O_5PS$, M_r 373.4, *mp* 50–51 °C, vapor pressure 220 µPa at 50 °C, consists of colorless crystals which are practically insoluble in water but soluble in acetone, ethyl acetate, and toluene [9, p. 477], [14, p. 233].

Pyrazophos is produced by condensation of cyanoacetic acid hydrazide with 2-formylacetoacetic acid to form ethyl 2-hydroxy-5-methylpyrazolo[1,5-α]pyrimidine-6-carboxytate followed by reaction with (*O,O*-diethyl) chlorothiophosphate [72].

Pyrazophos (announced in 1970) is a systemic fungicide with preventative and curative properties. Its spectrum of activity is confined to the powdery mildews, and it is used on cucurbits, apples, and other crops. Pyrazophos has side effects against some insect pests. Resistance in cucumber powdery mildew was detected in greenhouses after several years of use, but resistant isolates were less pathogenic [33, p. 133].

Trade Name. Curamil (AgrEvo).

8.2. Benzimidazoles

The systemic benzimidazole fungicides were originally developed as anthelmintics and include the derivatives benomyl, thiophanate methyl, thiabendazole, carbendazim, and fuberidazole. Benomyl is the most important, followed by thiophanate methyl; together they account for 75 % of all sales of benzimidazole fungicides. They have a broad spectrum of activity against plant-pathogenic fungi in the classes Ascomycetes, Deuteromycetes, and Basidiomycetes. However, they are particularly prone to development of resistance, which has led to a decline in their use for many crops. Nevertheless, they continue to be the most important group of systemic fungicides, in terms of world sales. Benzimidazoles act by binding to tubulin, a protein found in the microtubules [10, p. 299].

Benomyl [*17804-35-2*], methyl [1-(butylcarbamoyl)-1*H*-benzimidazol-2-yl]carbamate, $C_{14}H_{18}N_4O_3$, M_r 290.3, decomposes on heating without melting, is a colorless crystalline solid which is practically insoluble in water but soluble in heptane, chloroform and dimethylformamide [9, p. 37], [13, p. 117], [14, p. 175].

Benomyl is produced by reaction of carbendazim with butyl isocyanate [73].

Benomyl, introduced commercially in 1968, is used as a foliar fungicide with preventative and curative properties against a large range of diseases including *Botrytis* of grapes, soft fruit, and vegetables; scab and powdery mildew of deciduous fruit; and leaf spot diseases of field crops. It is also used as a post-harvest fungicide, a trunk injection for the control of Dutch elm disease, and for dipping planting material in pineapples and sugar cane. The activity in vivo can be ascribed to its hydrolysis product carbendazim described below.

Trade Name. Benlate (Du Pont).

Thiophanate methyl [*23564-05-8*], dimethyl 4,4′-(*o*-phenylene)bis(3-thioallophanate), $C_{12}H_{14}N_4O_4S_2$, M_r 342.4, *mp* 172 °C (decomp.), is a colorless crystalline solid which is sparingly soluble in water and only slightly soluble in acetone, chloroform, and methanol [9, p. 533], [14, p. 173].

Thiophanate methyl is produced by reaction of *o*-phenylenediamine and methoxycarbonyl isothiocyanate [74].

Thiophanate methyl, introduced in 1969 by Nippon Soda, is used as a preventative and curative fungicide. It is applied as a foliar fungicide, seed treatment, postharvest treatment, and soil drench on a wide range of crops including deciduous fruit, stone fruit, vegetables, grapes, sugar beet, rice, and turf. The thiophanate molecule is degraded in the plant to carbendazim, the active moiety.

Trade Names. Topsin M, (Nippon Soda); Mildothane (Rhône-Poulenc); Cycosin (Cyanamid).

Carbendazim [*10605-21-7*], methyl (1*H*-benzimidazol-2-yl)carbamate, $C_9H_9N_3O_2$, M_r 191.2, *mp* 310 °C (decomp.), vapor pressure < 100 nPa at 20 °C, is a colorless powder which is sparingly soluble in all solvents [9, p. 89], [14, p. 175].

Carbendazim is produced by the reaction of *o*-phenylenediamine with methoxycarbonylcyanamide or with methoxycarbonyl isocyanide dichloride (formed from cyanogen chloride, phosgene, and methanol) in the presence of a base [75], [76].

Carbendazim was introduced in 1973 and has a spectrum of activity and uses similar to benomyl and thiophanate methyl.

Trade Names. Bavistan (BASF); Derosal, Troika (AgrEvo); Delsene (Du Pont).

Fuberidazole [*3878-19-1*], 2-(2-furyl)benzimidazole, $C_{11}H_8N_2O$, M_r 184.2, *mp* 292 °C (decomp.), is a fine crystalline powder which is slightly soluble in water, soluble in toluene, and fairly soluble in dichloromethane, light petroleum, 2-propanol, 0.1 M hydrochloric acid, and 0.1 M sodium hydroxide [22, p. 632].

Fuberidazole is produced by reaction of *o*-phenylenediamine in copper acetate-containing methanol with furfural to give the copper salt of the desired compound, from which the free compound is liberated by treatment with hydrogen sulfide [77].

Fuberidazole (announced in1968) is used in seed treatment for control of *Fusarium* spp. in cereals, only in combination with other fungicides.

Trade Names. Baytan, Sibutol (Bayer).

Thiabendazole [*148-79-8*], 2-(1,3-thiazol-4-yl)benzimidazole, $C_{10}H_7N_3S$, M_r 201.2, *mp* 304 – 305 °C, is a colorless powder which is moderately soluble in water (pH dependent) and soluble in most organic solvents [22, p. 1183].

Thiabendazole is produced by heating thiazolyl-2-formamide with *o*-phenylenediamine in the presence of polyphosphoric acid [78].

Thiabendazole (announced in 1968) is used to control *Aspergillus*, *Botrytis*, *Cenospora*, *Cellotrichum*, *Corticum*, *Diaposthe*, *Dipodia*, and *Fusarium* in asparagus, avocados, bananas, barley, and beans. It is also used to control storage diseases of fruit and vegetables.

Trade Names. Mertect, Tecto, Storite (Merck, DowElanco); Decco (Elf Atochem); LSP (Gustafson).

8.3. Carboxanilides

The systemic antifungal properties of carboxin and oxycarboxin were discovered in the mid-1960s. These compounds and the related substance pyracarbolid act only against plant pathogens of the class Basidiomycetes. They interfere with respiration by inhibiting succinate oxidation [16, p. 155].

Carboxin [*5234-68-4*], 5,6-dihydro-2-methyl-1,4-oxathiine-3-carboxanilide, $C_{12}H_{13}NO_2S$, M_r 235.3, *mp* 91.5 – 92.5 °C, is a colorless solid which is practically insoluble in water but soluble in acetone, dimethyl sulfoxide, ethanol, and methanol [9, p. 95], [13, p. 104], [14, p. 199].

Carboxin is produced by reaction of 2-chloro-3-oxobutyricanilide with 2-mercaptoethanol, followed by acid-catalyzed ring closure with elimination of water [79].

Carboxin (announced in 1966) is used as a seed treatment for the control of smuts and bunts on cereals and for the control of *Rhizoctonia* spp. on cotton, vegetables, and groundnuts. Resistance in *Ustilago nuda* has been reported in samples isolated from barley varieties in France [80].

Trade Names. Vitavax (Uniroyal); Oxatin (Dichem); Kemikay (Kemira FC).

Flutolanil [*66332-96-5*], 3′-isopropoxy-α,α,α-trifluoro-*o*-toluanilide, $C_{17}H_{16}F_3NO_2$, M_r 323.3, *mp* 102 – 103 °C, vapor pressure 1.77 mPa at 20 °C, consists of colorless crystals which are practically insoluble in water but soluble in chloroform and methanol [9, p. 287].

Flutolanil is produced by reaction of 2-(trifluoromethyl)benzoyl chloride with 3-isopropoxyaniline [81].

Flutolanil (announced in 1981) acts against Basidiomycetes. It is used as a foliar fungicide for the control of *Typhula* on barley and sheath blight on rice, as well as a seed dressing against *Rhizoctonia solani* on potatoes and cucurbits.

Trade Names. Moncut (Nihon Nohyaku); Prostar (AgrEvo, Nihon Nohyaku).

Mepronil [*55814-41-0*], 3′-isopropoxy-*o*-toluanilide, $C_{17}H_{19}NO_2$, M_r 269.3, *mp* 92 – 93 °C, consists of colorless crystals which are slightly soluble in water and soluble in most organic solvents [22, p. 787].

Mepronil is produced by reaction of 3-isopropoxyaniline with 2-methylbenzoyl chloride or with 2-methylbenzoic acid in the presence of phosphorous trichloride and triethylamine [82].

Mepronil (announced in 1979) inhibits succinic acid oxidation during metabolic respiration. It is used to control diseases caused by *Basidiomycetes* in rice, cereals, potatoes, and vegetables.

Trade Name. Basitac (Kumiai).

Thifluzamide [*130000-40-7*], 2′,6′-dibromo-2-methyl-4′-trifluoromethoxy-4-trifluoromethyl-1,3-thiazole-5-carboxanilide,

$C_{13}H_6Br_2F_6N_2O_2S$, M_r 528.1, *mp* 177.9 – 178.6 °C, is a colorless to light brown powder which is sparingly soluble in water [22, p. 1191].

Thifluzamide is produced by reaction of 2-chloro-3-carbonyl-4-trifluoroethyl butylate with thioacetamide in DMF; the resulting thiazolecarboxylate is converted in two steps to thifluzamide [83].

Thifluzamide (announced in 1992) inhibits succinate dehydrogenase in the tricarboxylic acid cycle of fungi. It is used to control a wide range of *Basidiomycetes* fungi on rice, cereals, field crops, and turf by foliar application and as a seed treatment.

*Trade Name.*Not yet announced (Rohm & Haas).

8.4. Phenylamides

Discovered in the mid-1970s and previously known as acylalanines, the phenylamides are highly active systemic fungicides which act specifically against Peronosporales (Oomycetes). They include the compounds furalaxyl, metalaxyl, ofurace, oxadixyl, benalaxyl, and cyprofuram, which all have preventative, curative, and eradicative properties. They are prone to development of resistance, which has been observed in a number of target pathogens including those affecting cucumbers, grapevines, and potatoes.

Metalaxyl [*57837-19-1*], methyl ester of *N*-(2-methoxyacetyl)-*N*-(2,6-xylyl)-DL-alanine, $C_{15}H_{21}NO_4$, M_r 279.3, *mp* 71.8 – 72.3 °C, vapor pressure 293 µPa at 20 °C, consists of colorless crystals which are slightly soluble in water but readily soluble in benzene, dichloromethane, and methanol [9, p. 352], [15, p. 410].

Metalaxyl is produced by reaction of 2,6-dimethylaniline with an excess of methyl 2-bromopropionate in the presence of sodium bicarbonate, followed by acetylation with methoxyacetyl chloride [84].

Metalaxyl (announced in 1977) is used as a seed treatment, foliar spray, soil application, or postharvest fungicide. It is used as a seed dressing to control *Pythium* damping-off and systemic downy mildews which occur on brassicas, sunflowers, peas, and tropical *Gramineae.* As a foliar fungicide, it is used to control downy mildew and late blight on a wide range of crops including vegetables, grapes, and potatoes. Applied to the soil, it is used to control rot of the root and stem base of many crops, caused by *Pythium* and *Phytophthora* spp.

For foliar use, metalaxyl is available only in prepacked mixtures with contact fungicides, to reduce the risk of resistance and broaden the spectrum of activity.

Trade Names. Ridomil, (Novartis); Milor (Rotam).

Oxadixyl [*77732-09-3*], 2-methoxy-*N*-(2-oxo-1,3-oxazolidin-3-yl)-*N*-(2,6-xylyl)-acetamide, $C_{14}H_{18}N_2O_4$, M_r 278.3, *mp* 104 – 105 °C, vapor pressure 3.3 mPa at 20 °C, consists of colorless crystals which are slightly soluble in water but readily soluble in acetone, dimethyl sulfoxide, and ethanol [29, p. 755].

Oxadixyl is produced by intramolecular condensation of 1-chloroethyl-2-(methoxyacetyl)-2-(2,6-xylyl)-hydrazine carboxylate with sodium hydride [85].

Oxadixyl (announced in 1983) has a similar spectrum of activity to metalaxyl. It is used mostly as a foliar fungicide in mixtures with

contact fungicides and cymoxanil. It is also employed as a seed and soil treatment.
Trade Names. Sandofan, (Novartis); Anchor (Gustafson).

Ofurace [*58810-48-3*], α-[2-chloro-*N*-(2,6-xylyl)acetamido]-γ-butyrolactone, $C_{14}H_{16}ClNO_3$, M_r 281.74, *mp* 145 – 146 °C, vapor pressure 0.13 mPa at 20 °C, consists of colorless crystals which are practically insoluble in water but soluble in chloroform, acetone, ethyl acetate, and cyclohexanone [15, p. 413].

Ofurace is produced by refluxing 3-*N*-(2,6-dimethylphenyl)amino-γ-butyrolactone with chloroacetyl chloride in the presence of pyridine [86].

Ofurace shows a similar spectrum of activity to metalaxyl and is used as a foliar fungicide in mixtures with contact fungicides on crops such as potatoes, grapes, and vegetables.
Trade Names. Vamin, Patafol (AgrEvo).

Benalaxyl [*71626-11-4*], methyl *N*-phenylacetyl-*N*-(2,6-xylyl)-DL-alaninate, $C_{20}H_{23}NO_3$, M_r 325.4, *mp* 78 – 80 °C, is a colorless solid which is slightly soluble in water, sparingly soluble in hexane and saturated hydrocarbons, and soluble in most other organic solvents [22, p. 87].

Benalaxyl is produced by reaction of the methyl ester of *N*-(2,6-xylyl)-DL-alanine with benzoyl chloride in the presence of a base [87].

Benalaxyl (announced in 1981) inhibits nucleic acid RNA polymerase. It is used to control *Oomycetes*, particularly fungi of the family *Peronosporaceae*, *Phytophthora*, *Plasmopara*, *Pseudoperonospora*, *Sclerospora*, *Bremia*, and *Phythium* spp. Some uses include control of late blights of potatoes and tomatoes and downy mildew of hops, vines, lettuce, onions, and other crops.
Trade Name. Galben (Isagro).

Furalaxyl [*57646-30-7*], methyl *N*-(2-furoyl)-*N*-(2,6-xylyl)-DL-alaninate, $C_{17}H_{19}NO_4$, M_r 301.3, *mp* 70 °C, consists of colorless crystals which are sparingly soluble in water, and soluble in many organic solvents [22, p. 634].

Furalaxyl is produced by reaction of *N*-methylpropionate-2,6-dimethylaniline in toluene and DMF with 2-furancarbonyl chloride [88].

Furalaxyl (announced in 1977) is used to control soil-borne diseases caused by *Phytophthora* and *Pythium* spp., and other *Oomycetes* on ornamentals.
Trade Name. Fongarid (Novartis).

Metalaxyl-M [*70630-17-0*], methyl *N*-(methoxyacetyl)-*N*-(2,6-xylyl)-D-alaninate, $C_{15}H_{21}NO_4$, M_r 279.3, *mp* -38.7 °C, is a pale yellow to light brown viscous liquid which is moderately soluble in water and miscible with many organic compounds [22, p. 794].

Matalaxyl-M is produced by reaction of 2,6-dimethylaniline with methyl 2-bromopropionate in the presence of sodium carbonate, followed by acetylation with methyloxyacetyl chloride and separation of the isomers [89].

Matalaxyl-M (announced in 1996) inhibits protein synthesis in fungi by interference with the synthesis of ribosomal RNA. It is used to

control diseases caused by air- and soil-borne *Peronosporales* on a wide range of temporate, subtropical, and tropical crops.
Trade Names. Apron XL, Ridomil Gold (Novartis).

8.5. Phosphites

The phosphites are a group of fungicides with unique systemic properties because they are translocated both acropetally and basipetally in the plant; important examples are fosetyl Al and its degradation product, phosphorous acid.

Fosetyl Al [*39148-24-8*], aluminum tris(ethyl phosphite), $C_6H_{18}AlO_9P_3$, M_r 354.1, decomposes above 200 °C, consists of colorless crystals which are soluble in water but practically insoluble in most organic solvents [9, p. 294], [15, p. 407].

Fosetyl Al is produced by reaction of aluminum nitrate with an aqueous solution of sodium ethyl phosphite [90] or by reaction of ethyl phosphite and hydrargillite [$Al(OH)_3$] at 60 °C [91].

Fosetyl Al (announced in 1977) is used as a seed treatment, foliar fungicide, trunk injection, and soil treatment. Its spectrum of activity is largely confined to the Oomycetes, but it is not sufficiently active against all the important pathogens of this class, e.g., *Phytophthora infestans* of potato. As a seed treatment, it is used against downy mildew of peas. It is applied as a foliar spray to control airborne downy mildew of crops such as grapes and vegetables and to control root rot disease of pineapples, strawberries, and subtropical crops. It is also effective as a tree trunk injection in the control of soil-borne *Phytophthora* spp. of tree crops such as avocado because of its basipetal properties.
Trade Name. Aliette (Rhône-Poulenc).

Figure 1. Biosynthesis of ergosterol from lanosterol showing the three reactions inhibited by sterol biosynthesis inhibitor (SBI) fungicides

8.6. Inhibitors of Sterol Biosynthesis

Ergosterol is a principal sterol of most fungi and is indispensable for membrane stabilization. Most species of Ascomycetes, Basidiomycetes, and Deuteromycetes synthesize ergosterol from acetic acid. Sterol biosynthesis inhibitors (SBI) are thus active against plant pathogens of these classes, but not of Oomycetes which depend on an exogenous supply of suitable sterols. They block the multistep conversion of lanosterol to ergosterol mainly at the three positions shown in Figure 1. Many compounds such as substituted triazoles, imidazoles, pyridines, pyrimidines, and piperazines inhibit the cytochrome P450 assisted C-14-demethylation step. Morpholine and piperidine derivatives, however, inhibit the $\Delta^8 \rightarrow \Delta^7$-isomerization and can also block the Δ^{14}-reduction [92].

8.6.1. Triazoles

Triazole fungicides are used for foliar and seed treatment; they have protective and curative properties. They can be used alone or in mixtures with other fungicides.

Triadimefon [*43121-43-3*], 1-(4-chlorophenoxy)-3,3-dimethyl-1-(1*H*-1,2,4-triazol-1-yl)-2-butanone, $C_{14}H_{16}ClN_3O_2$, M_r 293.8, *mp* 82.3 °C, vapor pressure < 100 µPa at 20 °C, is a colorless solid which is practically insoluble in water but soluble in cyclohexanone, dichloromethane, 2-propanol, and toluene [9, p. 539], [14, p. 208], [92, p. 41].

Triadimefon can be produced by dichlorination of pinacolone followed by substitution with sodium *p*-chlorophenoxide and triazole in a one-pot reaction [93].

Triadimefon (announced in 1973) is used as a foliar spray for the control of powdery mildew and rust diseases of cereals, coffee, grapes, stone fruit, vegetables, and ornamentals. In the plant, triadimefon is converted into triadimenol.
Trade Name. Bayleton (Bayer).

Triadimenol [*55219-65-3*], 1-(4-chlorophenoxy)-3,3-dimethyl-1-(1*H*-1,2,4-triazol-1-yl)butan-2-ol, $C_{14}H_{18}ClN_3O_2$, M_r 295.8, *mp* 121 – 127 °C, vapor pressure < 1 mPa at 20 °C, consists of colorless crystals which are practically insoluble in water but soluble in dichloromethane, cyclohexane, and 2-propanol [9, p. 540], [92, p. 47].

Triadimenol is produced by reduction of triadimefon with aluminum isopropoxide [94].

Triadimenol (announced in 1977) is used as a seed treatment and foliar fungicide. As a seed dressing, it is used on cereals primarily for the control of powdery mildew and rust diseases but also for *Rhynchosporium secalis* on barley. It is used as a foliar fungicide to control powdery mildew in grapes, vegetables, hops, sugar beet, and tobacco, as well as banana sigatoka and coffee rust.
Trade Names. Baytan, Bayfidan, Silvacur (Bayer).

Bitertanol [*55179-31-2*], *rac*-1-(biphenyl-4-yloxy)-3,3-dimethyl-1-(1*H*-1,2,4-triazol-1-yl)-butan-2-ol, $C_{20}H_{23}N_3O_2$, M_r 337.4, *mp* 123 – 129 °C, vapor pressure 1 µPa at 20 °C, consists of colorless crystals which are practically insoluble in water but soluble in dichloromethane and partially soluble in toluene and 2-propanol [9, p. 54], [92, p. 47].

The production of bitertanol is similar to that of triadimenol [94].

Bitertanol (announced in 1977) is used as a foliar fungicide for the control of leaf spot diseases of groundnuts as well as apple scab and *Sclerotinia* spp. on stone fruit. As a seed dressing on wheat, it is used to control dwarf

bunt (*Tilletia controversa*), *Fusarium nivale,* and *Septoria nodorum*.
Trade Names. Baycor, Sibutol (Bayer).

Propiconazole [*60207-90-1*], (±)-1-[2-(2,4-dichlorophenyl)-4-propyl-1,3-dioxolan-2-ylmethyl]-1*H*-1,2,4-triazole, $C_{15}H_{17}Cl_2N_3O_2$, M_r 342.2, n_D^{20} 1.5468, *bp* 180 °C at 13.3 Pa, vapor pressure 133 µPa at 20 °C, is a yellowish viscous liquid which is practically insoluble in water but readily soluble in acetone, methanol, and 2-propanol [9, p. 468], [92, p. 44].

Propiconazole can be produced by ketalization of 2-bromo-2′,4′-dichloroacetophenone with 1,2-pentanediol, followed by nucleophilic substitution with sodium 1,2,4-triazolide in dimethylformamide at 160 °C [95].

Propiconazole (announced in 1979) is a broad-spectrum foliar fungicide used to control a range of cereal diseases, including powdery mildew, rust, *Septoria* spp., *Rhynchosporium,* and net blotch. It is also used against banana sigatoka, coffee rust, and various diseases of turf, rice, peanuts, pecans, maize, stone fruit, and other crops.
Trade Names. Tilt (Novartis); Radar (Zeneca).

Penconazole [*66246-88-6*], 2-(2,4-dichlorophenyl)-1-(1*H*-1,2,4-triazol-1-yl)pentane, $C_{13}H_{15}Cl_2N_3$, M_r 284.2, *mp* 60 °C, vapor pressure 0.21 mPa at 20 °C, consists of colorless crystals which are practically insoluble in water but soluble in most organic solvents [92, p. 40].

Penconazole can be produced by alkylation of 2,4-dichlorophenylacetonitrile with bromopropane, followed by conversion of the nitrile to the acetate. Reduction with lithium aluminum hydride gives the corresponding alcohol, which is first reacted with methanesulfonyl chloride and then with sodium triazolide [96]. An alternative synthesis is the reaction of 2′,4′-dichlorobutyrophenone with triazolylmethyl phosphonate, followed by hydrogenation [97].

Penconazole (announced in 1983) is used as a foliar fungicide to control powdery mildew of pome fruits, grapes, stone fruit, tobacco, vegetables, and ornamentals; scab of apples and pears; and black rot of grapes.
Trade Name. Topas (Novartis).

Flutriafol [*76674-21-0*], (*RS*)-2,4′-difluoro-α-(1*H*-1,2,4-triazol-1-ylmethyl)benzhydryl alcohol, $C_{16}H_{13}F_2N_3O$, M_r 301.3, *mp* 130 °C, vapor pressure 400 nPa at 20 °C, consists of colorless crystals which are practically insoluble in water but soluble in acetone, dichloromethane, methanol and xylene [92, p. 50].

Flutriafol is produced by reaction of 2,4′-difluorobenzophenone and trimethyloxosulfonium iodide; the resulting epoxide is then opened by triazole in the presence of a base [98].

Flutriafol (announced in 1983) is used as a foliar fungicide to control diseases such as powdery mildew, rust, *Rhynchosporium secalis, Helminthosporium,* and *Septoria* spp. It is also employed as a seed treatment on cereals.
Trade Names. Impact, Vincit (Zeneca).

Flusilazole [*85509-19-9*], bis(4-fluorophenyl)(methyl)(1*H*-1,2,4-triazol-1-ylmethyl) silane, $C_{16}H_{15}F_2N_3Si$, M_r 315.38, *mp* 55 °C, is a white crystalline solid which is practically insoluble in water but soluble in many organic solvents [22, p. 603].

Flusilazole can be produced by addition of butyllithium to a solution of chloromethyldi-

chlorosilane and 1-bromo-4-fluorobenzene and subsequent reaction with triazole [99].

Flusilazole (announced in 1984) is a broad-spectrum foliar fungicide which is used for the control of powdery mildew, rust, and leaf spot diseases of cereals; black rot and powdery mildew of grapes; and powdery mildew and scab of apples.

Trade Names. Punch, Nustar, Olymp, Sanction, Captan (Du Pont).

Hexaconazole [*79983-71-4*], (*RS*)-2-(2,4-dichlorophenyl)-1-(1*H*-1,2,4-triazol-1-yl)hexan-2-ol, $C_{14}H_{17}Cl_2N_3O$, M_r 314.2, *mp* 111 °C, vapor pressure 0.02 mPa at 20 °C, consists of colorless crystals which are practically insoluble in water but soluble in many organic solvents [29, p. 562].

Hexaconazole is produced by reaction of 1-(2,4-dichlorophenyl)pentan-2-one and trimethyloxosulfonium iodide, followed by opening of the resulting epoxide with triazole in the presence of a base [100].

Hexaconazole (announced in 1986) is being developed as a broad-spectrum foliar fungicide. It is used for the control of powdery mildew and black rot of grapes, powdery mildew and scab of apples, coffee rust, and leaf spot diseases of groundnuts [100, p. 19]

*Trade Names.*Contaf (Rollis); Anvil, Planeta (Zeneca).

Diniconazole [*76714-88-0*], (*E*)-1-(2,4-dichlorophenyl)-4,4-dimethyl-2-(1*H*-1,2,4-triazol-1-yl)pent-1-en-3-ol, $C_{15}H_{17}Cl_2N_3O$, M_r 326.2, *mp* 134 – 156 °C, is a white crystalline solid which is slightly soluble in water and partially soluble in acetone or methanol [92, p. 48].

Diniconazole is produced by condensation of 2,4-dichlorobenzaldehyde and triazolylpinacolone, followed by photochemical isomerization of the *E* – *Z* mixture to the *E* isomer and reduction with sodium borohydride [102].

Diniconazole (announced in 1986) is being developed as a foliar spray and a seed treatment. As a foliar spray, it controls leaf spot, rust, and white mold of groundnuts; powdery mildew of apples, grapes, and small grain cereals; and rust diseases of apples and cereals. As a seed treatment, it controls bunts and smuts of cereals.

Trade Names. Spotless, Sumi-8 (Sumitomo).

Myclobutanil [*88671-89-0*], 2-(4-chlorophenyl)-2-(1*H*-1,2,4-triazol-1-ylmethyl)hexanenitrile, $C_{15}H_{17}ClN_4$, M_r 288.8, *mp* 63 – 68 °C, *bp* 202 – 208 °C at 133 Pa, vapor pressure 213 mPa, is a pale-yellow solid which is practically insoluble in water but soluble in ethanol, benzene, ethyl acetate, and acetone [22, p. 854].

Myclobutanil is produced by alkylation of 4-chlorophenylacetonitrile with butyl chloride, followed by treatment with dibromomethane and sodium hydroxide in dimethyl sulfoxide. The resulting intermediate is then reacted with the potassium salt of 1,2,4-triazole in dimethylformamide [103].

Myclobutanil (announced in 1986) acts against powdery mildew and scab of apples, as well as black rot and powdery mildew of grapevines. It is also being tested as a cereal seed dressing [101, p. 55].

Trade Name. Systhane (Rohm & Haas).

Tebuconazole [*80443-41-0*], (*RS*)-1-(4-chlorophenyl)-4,4-dimethyl-3-(1*H*-1,2,4-triazol-1-ylmethyl)pentan-3-ol, $C_{16}H_{22}ClN_3O$, M_r 307.81, *mp* 104.7 °C, consists of colorless crystals which are practically insoluble in water but soluble in many organic solvents [22, p. 1144].

Tebuconazole is produced by opening the 2-*tert*-butyl-2-(4-chlorophenethyl) oxirane with 1,2,4-triazole in the presence of a base [104].

Tebuconazole (announced in 1986) is being developed as a foliar spray and seed treatment against a range of fungal pathogens. It is an effective seed treatment against bunts, smuts, and *Septoria* spp. on cereals. As a foliar spray, it acts against rust, powdery mildew, and leaf and head diseases and is also being tested on a range of field crops [101, p. 41].

Trade Names. Folicur, Raxil, Elite, Horizon, Lynx, Matador (Bayer).

Cyproconazole [*94361-06-5*], (2*RS*,3*RS*)-2-(4-chlorophenyl)-3-cyclopropyl-1-(1*H*-1,2,4-triazol-1-yl)butan-2-ol, $C_{15}H_{18}ClN_3O$, M_r 291.8, *mp* 103 – 105 °C, vapor pressure 34.7 µPa at 20 °C, consists of colorless crystals which are practically insoluble in water but readily soluble in acetone, ethanol, xylene, and dimethyl sulfoxide [101, p. 33].

Cyproconazole is produced by reaction of 1-(4-chlorophenyl)-2-cyclopropylethanone with methyl iodide in the presence of sodium hydride followed by treatment with dodecyldimethylsulfonium methyl sulfate to yield the epoxide intermediate which is then opened by triazole in the presence of a base [105].

Cyproconazole (announced in 1986) is being developed as a foliar spray against rust diseases of cereals and coffee; powdery mildews of cereals, fruit trees and grapes; leaf spot diseases of peanuts and sugar beet; apple scab; and white mold.

Cyproconazole is a broad spectrum foliar fungicide with activity against diseases caused by powdery mildews, rusts, *Monilinia, Cercospora*, *Venturia, Rhizoctonia* and *Sclerotium*. It shows long-lasting protective as well as curative and eradicative activity. It penetrates into the plant very rapidly and is translocated acropetally. Crops on which it is used or under development include cereals, fruit trees, grapevines, peanuts, sugar beet, bananas, and coffee.

Trade Names. Alto (Novartis); Shandon (Barclay).

Difenconazole [*119446-68-3*], 3-chloro-4-[4-methyl-2-(1*H*-1,2,4-triazol-1-ylmethyl)-1,3-dioxolan-2-yl]phenyl-4-chlorophenyl ether, CGA-169374, $C_{19}H_{17}Cl_2N_3O_3$, M_r 406.3, *mp* 76 °C, vapor pressure 0.12 µPa at 20 °C, is a white crystalline solid that is practically insoluble in water but very soluble in most organic solvents [29, p. 328].

Difenconazole is produced by ketalization of 2-bromo-2′-chloro-4′-(4-chlorophenyl)acetophenone with 1,2-propanediol, followed by nucleophilic substitution with sodium 1,2,4-triazolide in dimethylformamide under reflux [106].

Difenconazole (announced in 1988) is a broad-spectrum foliar and seed treatment fungicide. It shows translaminar systemicity and provides long-lasting protective and curative activity against Ascomycetes, Deuteromycetes, and Basidiomycetes.

Difenconazole is particularly effective against pathogens such as *Alternaria,* and pathogen complexes against which other SBIs are relatively weak. The spectrum includes species of *Septoria, Cercospora, Cercosporidium, Ascochyta, Alternaria, Ramularia, Venturia, Guignardia, Phoma, Collectotrichum,* rust fungi, and powdery mildews).

The crops on which it is being developed include wheat, sugar beet, peanuts, potatoes, pome fruit, grapes, and vegetables.

Trade Names. Score, Dividend (Novartis).

Azaconazole [*60207-31-0*], 1-[{2-(2,4-dichlorophenyl)-1,3-dioxolan-2-yl}methyl]-*H*-1,2,4-triazole, $C_{12}H_{11}Cl_2N_3O_2$, M_r 300.1, *mp* 112.6 °C, is a beige to brown colored powder

which is moderately soluble in water and hexane and readily soluble in acetone, methanol, and toluene [22, p. 58].

Azoconazole is produced by reaction of 1*H*-1,2,4-triazole with bromomethyl-2,4-dichlorophenyl ethylene ketal [107].

Azoconazole (announced in 1983) is used against wood-destroying and sapstain fungi. It is also used as a disinfectant in mushroom cultivation and on storage boxes for fruit and vegetables.

Trade Names. Rodewod, Safetray SL (Jansson).

Bromuconazole [*116255-48-2*], 1-[(2*RS*, 4*RS*; 2*RS*, 4*SR*)-4-bromo-2-(2,4-dichlorophenyl)tetrahydrofurfursaveyl]-1*H*-1,2,4-triazole, $C_{13}H_{12}BrCl_2N_3O$, M_r 377.1, *mp* 84 °C, is a colorless powder which is sparingly soluble in water and moderately soluble in organic solvents [22, p. 152].

Bromuconazole is produced by reaction of 1-bromomethoxyacetylene in toluene with ethylmagnesium bromide in THF, followed by the addition of 2,4-dichlorobenzoylmethyl chloride to give 2,4-dichlorophenyl-2′-chloromethyl-2′-hydroxy-2′-bromomethoxyacetylene. The product is then hydrogenated and treated with 4-methylphenylsulfonic acid in toluene to give 2-chloromethyl-2-(2,4-dichlorophenyl)-2,5-dihydrofuran, which is treated with 1,2,4-triazole in *N*-methylpyrrolidone in the presence of potassium carbonate to yield the desired product [108].

Bromuconazole (announced in 1990) is used against *Ascomycetes*, *Basidiomycetes* and *Fungi imperfecti* including *Alternaria*, *Fusarium*, black and yellow sigatoke, and *Pseudocercosporalia* spp. in cereals, fruits, vines, vegetables, tropical crops, turf, and ornamentals.

Trade Names. Granit, Vectra (Rhône-Poulenc).

Epoxiconazole [*106325-08-0*], (2*RS*, 3 *SR*)-1- [3-(2-chlorophenyl)-2, 3-epoxy-2- (4- fluorophenyl)propyl]-*H*-1,2,4-triazole, $C_{12}H_{17}ClFN_3O$, M_r 329.8, *mp*136.2 °C, consists of colorless crystals which are sparingly soluble in water, moderately soluble in *n*-heptane, and soluble in acetone, and dichloromethane [22, p. 79].

Epoxiconazole is produced by reaction of 2,4-dichlorobenzylphosphonium triphenylchloride with 4-chlorophenyl acetate and potassium *tert*-butoxide in refluxing methanol, and bromination of the resulting product, followed by epoxidation with 3-chloroperbenzoic acid [109].

Epoxiconazole (announced in 1990) is used as a broad-spectrum fungicide for control of diseases caused by *Ascomycetes, Basidiomycetes*, and *Deuteromycetes* in cereals, sugarbeet, peanuts, oilseed rape, and ornamentals.

Trade Name. Opus (BASF).

Fenbuconazole [*114369-43-6*], 4-(4-chlorophenyl)-2-phenyl-2-(1*H*-1,2,4-triazol-1-ylmethyl)butyronitrile, $C_{19}H_{17}ClN_4$, M_r 336.8, *mp* 124-126 °C, consists of colorless crystals which are sparingly soluble in water but readily soluble in common organic solvents [22, p. 508].

Fenbuconazole is produced by reaction of benzylnitrile with potassium hydride in toluene, followed by the addition of *p*-chlorophenethyl chloride in diemthylformamide to give α-[2-(*p*-chlorophenyl)ethyl]phenylacetonitrile. This is treated with bromomethane in dimethylsulfoxide in the presence of sodium hydrox-

ide to yield 1-bromo-2-cyano-2-phenyl-4-(*p*-chlorophenyl)butane, which upon heating with triazole, in KOH-containing dimethyl sulfoxide, yields fenbuconazole [110].

Fenbuconazole (announced in 1988) is used to control *Septoria* and *Puccinia* rusts, bunt, and smut and *Rhynchosporium secalis* on cereals; and powdery mildew and scab on many crops.
Trade Names. Inder (Rohm & Haas); Troika (AgrEvo).

Fluquinconazole [*136426-54-5*], 3-(2,4-dichlorophenyl)-6-fluoro-2-(1*H*-1,2,4-triazol-1-yl)quinazolin-4(3*H*)-one, $C_{16}H_8Cl_2FN_5O$, M_r 376.3, *mp* 184 – 192 °C, is a pale crystalline solid which is practically insoluble in water, moderately soluble in ethanol, and soluble in acetone, xylene, and dimethyl sulfoxide [22, p. 588].

Fluquinconazole is produced by reaction of 2-chloro-6-fluoro-*N*-3-*p*-chlorophenylquinazoline-4(3*H*)-one with 1,2,4-triazole in an inert solvent in the presence of potassium carbonate [111].

Fluquinconazole (announced in 1992) is used to control a wide range of *Ascomycetes*, *Deuteromycetee*, and *Basidiomycetes* by foliar application to broad-leaved and cereal crops.
Trade Names. Castellan, Vista (AgrEvo).

Metconazole [*125116-23-6*], (1*RS*,5*RS*; 1*RS*,5*SR*)-5-(4-chlorobenzyl)-2,2-dimethyl-1-(1*H*-1,2,4-trizol-1-ylmethyl)cyclopentanol, $C_{17}H_{22}ClN_3O$, M_r 319.8, *mp* 110-113 °C, is a colorless crystalline solid which is sparingly soluble in water but readily soluble in acetone, and methanol [22, p. 803].

Metconazole is produced by reaction of 3-dimethyl-2-oxocyclopentanecarboxylate in benzene with sodium hydride, followed by addition of 4-chlorobenzoyl chloride, and the thus obtained product decarboxylated by heating with hydrogen bromide [112].

Metconazole (announced in 1992) is applied post-emergence to control a wide range of foliar diseases on cereals and other crops.
Trade Name. Carambo (Cyanamid).

8.6.2. Imidazoles

Imidazole fungicides with protective and curative properties are used for foliar, postharvest, and seed treatment. They include the compounds prochloraz, imazalil, and triflumizole.

Prochloraz [*67747-09-5*], *N*-propyl-*N*-[-2-(2,4,6-trichlorophenoxy)ethyl]imidazole-1-carboxamide, $C_{15}H_{16}Cl_3N_3O_2$, M_r 376.7, *mp* 38.5 – 41 °C, vapor pressure 80 nPa at 20 °C, is a colorless crystalline solid which is practically insoluble in water but readily soluble in acetone, chloroform, diethyl ether, and toluene [9, p. 452], [92, p. 53].

Prochloraz is produced by reaction of 2-(2,4,6-trichlorophenoxy)ethyl bromide with propylamine, followed by phosgenation and formation of the substituted urea with imidazole [113].

Prochloraz (announced in 1977) is used as a foliar fungicide against a range of diseases occurring on cereals, field crops, fruit, vegetables, and turf. On cereals it is active against eye spot, net blotch, powdery mildew, and *Rhynchospo-*

rium and *Septoria* spp. Prochloraz is also employed as a postharvest treatment against storage diseases of tropical and subtropical fruit.
Trade Names. Sportak (AgrEvo); Eyetak (Barclay).

Imazalil [*35554-44-0*], allyl 1-(2,4-dichlorophenyl)-2-(imidazol-1-yl)ethyl ether, $C_{14}H_{14}Cl_2N_2O$, M_r 297.2, d^{23} 1.2429; n_D^{20} 1.5643, vapor pressure 9.3 µPa at 20 °C, is a brownish oil which is slightly soluble in water and freely soluble in organic solvents [9, p. 315], [14, p. 210], [92, p. 50].

Imazalil is produced by bromination of 2′,4′-dichloroacetophenone, followed by reduction with sodium borohydride to form an epoxide intermediate. The epoxide is opened with imidazole, and the resulting alcohol is then etherified [114].

Imazalil (announced in 1973) is active as a seed treatment against *Fusarium, Helminthosporium,* and *Septoria* spp. on cereals and as a postharvest fungicide against storage rot of fruit.
Trade Names. Fungaflor, Fungazil (Jansson); Deccozil (Elf Atochem); Nuzone (Wiebur-Ellis); Freshguard (FMC).

Pefurazoate [*101903-30-4*], pent-4-enyl *N*-furfuryl-*N*-imidazol-1-ylcarbonyl-DL-homoalaninate, $C_{18}H_{23}N_3O_4$, M_r 345.4, *bp* 235 °C (decomp.), is a pale brownish liquid which is slightly soluble in water but readily soluble in most organic solvents [22, p. 932].

Pefurazoate is produced by reaction of [*N*-(pent-4-enyloxy)carbonyl] butylfurfurylcarbamoyl chloride with imidazole in dimethyl sulfoxide containing triethylamine [115].

Pefurazote (announced in 1990) is used to control seed-borne fungal diseases, particularly *Fusarium moniliforme*, *Pyricutaria oryzae*, and *Cochliobulus miyaheanna*. It is also used for control of rice seedling blight caused by soil-borne pathogens.
Trade Name. Healthied (Hokko, Ube).

Triflumizole [*68694-11-1*], (*E*)-4-chloro-α,α,α-trifluoro-*N*-(1-imidazol-1-yl-2-propoxyethylidene)-*o*-toluidine, $C_{15}H_{15}ClF_3N_3O$, M_r 345.7, *mp* 63 °C, consists of colorless crystals which are sparingly soluble in water and hexane but highly soluble in chloroform, acetone, and acetonitrile [22, p. 1245].

Triflumizole is produced by reaction of 2-trifluoromethyl-4-chloropropoxyacetanilide with imidazole in the presence of phosphorous pentachloride [116].

Triflumizole (announced in 1982) is used to control *Gymnosporangium* and *Venturia* spp. in pome fruits, against powdery *Erysiphaceae* in fruit and vegetables, and against *Fusarium*, *Fulvia* and *Monilinia* spp. It is also used as a seed treatment against *Helminthosporium*, *Tilletia* and *Ustilago* spp. in cereals.
Trade Name. Trifmine (Nippon Soda).

8.6.3. Pyridines

Pyrifenox [*88283-41-4*], 2′,4′-dichloro-2-(3-pyridyl)acetophenone *O*-methyloxime, $C_{14}H_{12}Cl_2N_2O$, M_r 295.16, *bp* > 150 °C at 13.3 Pa, vapor pressure 1.9 mPa, is a tan liquid which is practically insoluble in water but soluble in organic solvents [29, p. 884].

Pyrifenox is produced by condensation of an alkyl ester of 2,4-dichlorobenzoic acid with ethyl 3-pyridylacetate, followed by reaction with *O*-methylhydroxylamine [118].

Pyrifenox (announced in 1986) has protective and curative properties. It is active as a foliar fungicide against powdery mildew of apples and grapes, apple scab, and groundnut leaf spot diseases.

Trade Names. Rondo, Furado (Novartis); Padigrol (Novartis, Nippon Kagoku).

8.6.4. Pyrimidines

Pyrimidine fungicides include the compounds fenarimol and nuarimol; they all show protective and curative properties, and are active primarily against powdery mildew fungi.

Fenarimol [*60168-88-9*], (±)-2,4′-dichloro-α-(5-pyrimidinyl)benzhydryl alcohol, $C_{17}H_{12}Cl_2N_2O$, M_r 331.2, *mp* 117 – 119 °C, vapor pressure 13 µPa at 25 °C, consists of colorless crystals which are practically insoluble in water but soluble in acetone and methanol [9, p. 257], [14, p. 214], [92, p. 29].

Fenarimol is produced by reaction of 2,4′-dichlorobenzophenone with 5-lithiopyrimidine at – 125 °C [117].

Fenarimol (announced in 1975) is used as a foliar spray for the control of powdery mildew of apples, cucurbits, grapes, and ornamentals, as well as apple scab.

Trade Name. Rubigan (Dow Elanco).

Cyprodinil [*121552-61-2*], 4-cyclopropyl-6-methyl-*N*-phenylpyrimidin-2-amine, $C_{14}H_{15}N_3$, M_r 225.3, *mp* 75.9 °C, is a beige powder which is fairly soluble in water and soluble in ethanol, acetone, toluene, *n*-hexane, and *n*-octanol [22, p. 319].

Cyprodinil is produced by cyclocondensation of phenylguanidinium carbonate with 1-cyclopropyl-1,3-butenedione [119].

Cyprodinil (announced in 1994) inhibits methionine biosynthesis. It is used as a foliar fungicide in cereals, grapes, pome fruits, stone fruits, strawberries, and vegetables and as a seed dressing on barley; it controls a wide range of pathogens, including *Pseudocercosporella herpotricloides*, *Erysiphe* spp., *Pyrenophora teres, Rhynchosporium* secalis*, Septoria nodorum.*

Trade Names. Unix, Chorus, Stereo, Switch (Novartis).

Dimethirimol [*5221-53-4*], 5-*n*-butyl-2-dimethylamino-4-hydroxy-6-methylpyrimidine, $C_{11}H_{19}N_3O$, M_r 109.3, *mp* 102 °C, consists of colorless needles which are moderately soluble in water and soluble in acetone, chloroform, ethanol, and xylene [22, p. 412].

Dimethirimol is produced by reaction of 5-*n*-butyl-4-hydroxy-6-methyl-2-methylthiopyrimidine with dimethylamine acetate [120].

Dimethirimol (announced in 1968) is used in soil application for control of powdery mildews in cucurbits, tobacco, capsicums, tomatoes, and some ornamentals.

Trade Name. Milcurb (Zeneca).

Nuarimol [*63284-71-9*], (±)-2-chloro-4′-fluoro-α-(pyrimidin-5-yl)benzhydryl alcohol, $C_{17}H_{12}ClFN_2O$, M_r 314.7, *mp* 126 – 127 °C, is a colorless crystalline solid which is sparingly soluble in water and readily soluble in acetone, methanol, and xylene [22, p. 889].

Nuarimol is produced by reaction of 5-bromopyrimidine with 4-fluorobenzoyl-2-chlorobenzene in the presence of butyllithium [121].

Nuaromil (announced in 1980) is used to control a wide range of pathogenic fungi, e.g., *Cerosporella* spp., *Septoria* spp., *Ustilago* spp., powdery mildew, leaf spot in cereals, both as foliar spray and as a seed treatment; powdery mildews on pome fruits, stone fruits, vines, and hops.
Trade Name. Trimidal (DowElanco).

Pyrimethanil [*53112-28-0*], *N*-(4,6-dimethylpyrimidin-2-yl)aniline, $C_{12}H_{13}N_3$, M_r 199.3, *mp* 96.3 °C, is a colorless crystalline solid which is sparingly soluble in water but soluble in most organic solvents [22, p. 1068].

Pyrimethanil is produced by reaction of 2-bromo-4,6-dimethylpyrimidine with aniline [122].

Pyrimethanil (announced in 1992) is used to control gray mold (*Botrytis cinerea*) on vines, fruit, vegetables, and ornamentals.
Trade Names. Scala, Mythos (AgrEvo).

8.6.5. Piperazines

Triforine [*26644-46-2*], 1,4-bis(2,2,2-trichloro-1-formamidoethyl)piperazine, $C_{10}H_{14}Cl_6N_4O_2$, M_r 435.0, *mp* 155 °C, vapor pressure 27 µPa at 25 °C, consists of colorless crystals which are practically insoluble in water but soluble in dimethylformamide or 1-methyl-pyrrolid-2-one [9, p. 553], [14, p. 213], [92, p. 26].

Triforine is produced by reaction of piperazine with (1,2,2,2-tetrachloroethyl)formamide in the presence of triethylamine [123].

Triforine (announced in 1969) is used as a foliar and postharvest fungicide. It is active against powdery mildew, rust, and leaf spot diseases of fruit, ornamentals, vegetables, and cereals.
Trade Name. Saprol (Cyanamid).

8.6.6. Morpholines

The morpholine fungicides include tridemorph, fenpropimorph, and fenpropidin. They are used as foliar fungicides with protective and curative properties for the control of powdery mildew and rust on cereals. Although the first representatives of this group were launched in the late 1960s, interest in them has been renewed because of the development of resistance to the C-14-demethylation inhibitors in powdery mildews. Morpholine fungicides are used alone and in mixtures with contact and systemic fungicides.

Tridemorph [*24602-86-6*], 2,6-dimethyl-4-tridecylmorpholine, $C_{19}H_{39}NO$, M_r 297.5, *bp* 134 °C at 66 Pa, vapor pressure 40 mPa at 20 °C, is a colorless oil which is practically insoluble in water but miscible with acetone, benzene, chloroform, and ethanol [9, p. 550], [13, p. 123], [14, p. 219], [92, p. 55].

Tridemorph is produced as the main product (60 – 70 %) in the reaction of tridecylamine and propylene oxide, followed by dehydration and cyclization in the presence of concentrated sul-

furic acid [124]. Other homologues ($n = 10$, 11, or 13) are also formed.

Tridemorph (announced in 1969) is used as a foliar fungicide for the control of powdery mildew of cereals.
Trade Name. Calixin (BASF).

Fenpropimorph [*67564-91-4*], (±)-*cis*-4-[3-(4-*tert*-butylphenyl)-2-methylpropyl]-2,6-dimethylmorpholine, $C_{20}H_{33}NO$, M_r 303.5, *bp* 120 °C at 6.6 Pa, n_D^{20} 1.4940, is a colorless oil which is practically insoluble in water but miscible with acetone, chloroform, and ethanol [9, p. 265], [92, p. 56].

Fenpropimorph is produced by reductive amination of 3-(4-*tert*-butylphenyl)-2-methylpropanal and *cis*-2,6-dimethylmorpholine [125].

Fenpropimorph (announced in 1979) is used as a foliar fungicide in cereals for the control of powdery mildew, rust, and *Rhynchosporium secalis*.
Trade Name. Corbel (BASF, Novartis).

Dimethomorph [*110488-70-5*], (*E,Z*)-4-[3-(4-chlorophenyl)-3-(3,4-dimethoxyphenyl)acryloyl]morpholine, $C_{21}H_{22}ClNO_4$, M_r 387.9, *mp* 127 – 148 °C, is a colorless crystalline solid that is practically insoluble in water, slightly soluble in acetone, toluene and methanol, and soluble in dichloromethane [47, p. 17].

Dimethomorph is produced by Friedel – Crafts acylation of vertrole with 4-chlorobenzoyl chloride, followed by condensation with triethyl phosphonoacetate in the presence of a base such as sodium hydride in dimethoxyethane. The resulting ethyl cinnamate is then converted to the corresponding morpholide [126].

Announced in 1988, dimethomorph is active against downy mildew fungi (Peronosporaceae) and the genus *Phytophthora*. It is being developed in mixtures with protectant fungicides for the control of downy mildew of grapevine and late blight of potato and tomato. It shows translaminar movement following foliar application as well as protectant, curative, and antisporulant activity.
Trade Names. Acrobat, Forum (Cyanamid).

Dodemorph acetate [*31717-87-0*], *N*-cyclododecyl-2,6-dimethylmorpholinium acetate, $C_{20}H_{39}NO_3$, M_r 341.5, *mp* 63-64 °C, is a colorless solid which is sparingly soluble in water and soluble in chloroform, ethanol, acetone, ethyl acetate, and cyclohexane [22, p. 449].

Dodemorph acetate is produced by reaction of 2,6-dimethyltetrahydro-1,4-oxazin with dodecyl ketone to give the corresponding enamine, followed by hydrogenation [127].

Dodemorph (announced in 1968) is used to control powdery mildews on roses and other ornamentals.
Trade Name. Meltatox (BASF).

8.6.7. Strobulins

The strobulins are a new group of broad-spectrum, systemic, preventive and eradicant fungicides active against a wide range of *Ascomycete* and *Deuteromycete* fungi, but especially *Botrytis* spp. and *Venturia* spp.

Azoxystrobin [*131860-33-8*], (*E*)-2-{2-[6-(2-cyanophenoxy)pyrimidin-4-yloxy]phenyl}-3-methoxyacrylate, $C_{22}H_{17}N_3O_5$, M_r 403.4, *mp* 116 °C, is a colorless solid which is sparingly soluble in water, hexane, and *n*-octanol, moderately soluble in methanol, toluene, and

acetone, and readily soluble in ethyl acetate, acetonitrile, and dichloromethane [22, p. 70].

Azoxystrobin is produced by reaction of 4,6-dichloropyrimidine with (*E*)-2-hydroxymethoxyacrylate in DMF containing potassium carbonate, followed by reaction with 2-cyanophenol in DMF containing potassium carbonate [128].

Azoxystrobin (announced in 1992) inhibits mitochondrial respiration by blocking electron transfer between cytochrome b and cytochtome c_1. It is used to control a wide range of pathogens.

Trade Names. Amistar, Heritage, Quadris (Zeneca).

Kresoxim-methyl [*143390-89-0*], methyl (*E*)-2-methoxyimino[α-(*o*-tolyloxy)-*o*-tolyl]acetate, $C_{18}H_{19}NO_4$, M_r 313.4, *mp* 97.2 – 101.7 °C, consists of colorless crystals which are sparingly soluble in water [22, p. 743].

Kresoxim-methyl is produced by by the Grignard reaction of 1-(2-methylphenoxy)-2-bromobenzene in THF with methyloxalylimidazole to give 2-(2-methyloxalylimidazole)phenylglyoxylic acid methyl ester, which upon reaction with methylhydroxylamine hydrochloride in methanol containing sodium carbonate yields the desired product [129].

Kresoxim-methyl (announced in 1992) is used to control scab in apples and pears and powdery mildew on apples, vines, cucurbits, and sugar beets.

Trade Names. Allegro, Stroby, Mentor (BASF).

Metominostrobin [*133408-50-1*], (*E*)-2-methoxyimino-*N*-methyl-2-(2-phenoxyphenyl)-acetamide, $C_{16}H_{16}N_2O_3$, M_r 284.3, *mp* 87 – 89 °C, consists of colorless crystals which are sparingly soluble in water but readily soluble in dichloromethane and chloroform [22, p. 1114].

Metominostrobin is produced by reaction of 1-bromo-2-phenoxybenzene with magnesium in THF in the presence of dibromethane, followed by chlorination with oxalyl chloride in THF, and amidation with methylamine in methanol [130].

Metominostrobin (announced in 1994) is used to control *Pyricularia orzyae* on rice.

Trade Name. Oribright (Shionogi).

8.7. Miscellaneous

Propamocarb [*24579-73-5*], propyl 3-(dimethylamino)propylcarbamate, $C_9H_{21}ClN_2O_2$, M_r 224.7, *mp* 45 – 55 °C (hydrochloride), vapor pressure 800 mPa at 25 °C; the hydrochloride is a colorless crystalline solid, which is hygroscopic and soluble in water, methanol, and dichloromethane [9, p. 461], [15, p. 404].

Propamocarb is produced by reaction of *N,N*-dimethylpropane-1,3-diamine with propyl chloroformate in the presence of a base, followed by treatment with hydrogen chloride [131].

Propamocarb (announced in 1978) is used as a soil and seed treatment, a dip treatment for bulbs and tubers, and a foliar fungicide. It should be used preventatively; its spectrum of activity is confined to Oomycetes.

Trade Names. Previcur, Banol (AgrEvo).

Isoprothiolane [*50512-35-1*], diisopropyl (1,3-dithiolan-2-ylidene)malonate, $C_{12}H_{18}O_4S_2$, M_r 290.4, *mp* 50 – 54.5 °C, *bp* 167 – 169 °C at 70 Pa, consists of colorless crystals which are slightly soluble in water [9, p. 328], [14, p. 198].

Isoprothiolane is produced by condensation of diisopropyl malonate with carbon disulfide in the presence of sodium hydroxide, followed by alkylation with 1,2-dichloroethane [81].

Isoprothiolane (announced in 1973) is used as a foliar spray and an "into-water treatment" for the control of rice blast. It is translocated to the leaves and heads after uptake by the roots. Resistant strains of *Pyricularia oryzae* have been detected in field populations in Japan.

Trade Name. Fuji-one (Nihon Nohyaku).

Pyroquilon [*57369-32-1*], 1,2,5,6-tetrahydro-4*H*-pyrrolo[3,2,1-*ij*]-quinolin-4-one, $C_{11}H_{11}NO$, M_r 173.2, *mp* 112 °C, vapor pressure 0.16 mPa at 20 °C, consists of colorless crystals which are practically insoluble in water but soluble in methanol, dichloromethane, benzene, and acetone [22, p. 1075].

Pyroquilon is produced by reaction of indoline and chloroacetyl chloride. The resulting intermediate is then cyclocondensed with dimethylformamide in the presence of phosphorus oxychloride and hydrogenated [132].

Pyroquilon (announced in 1979) is used in the preventive control of rice blast as a seed and seedling box treatment, and as an "into-water treatment" in the field. The mode of action is by inhibition of melanin synthesis; the lack of melanin prevents the fungus from penetrating the leaf.

Trade Names. Coratop, Fongorene (Novartis).

Hymexazol [*10004-44-1*], 5-methylisoxazol-3-ol, $C_4H_5NO_2$, M_r 99.15, *mp* 86 °C, vapor pressure < 133 mPa at 25 °C, consists of colorless crystals which are soluble in water and most organic solvents [9, p. 314], [14, p. 215], [15, p. 399].

Hymexazol is produced by reaction of ethyl 2-butynoate with hydroxylamine [133].

Hymexazol (announced in 1973) is used as a seed and soil treatment. It is active against seedling diseases caused by *Aphanomyces, Pythium* and *Fusarium* spp. It is used as a soil fungicide on ornamentals, rice, and sugar beet and as a seed dressing on sugar beet. It stimulates root growth in rice seedlings.

Trade Name. Tachigaren (Sankyo).

Tricyclazole [*41814-78-2*], 5-methyl-1,2,4-triazolo[3,4-*b*]-benzothiazole, $C_9H_7N_3S$, M_r 189.2, *mp* 187 – 188 °C, vapor pressure 27 µPa at 25 °C, is a crystalline solid which is slightly soluble in water, acetone, methanol, and xylene [9, p. 549], [14, p. 220].

Tricyclazole is produced by reaction of 2-hydrazino-4-methylbenzothiazole with triethyl orthoformate at 100 – 200 °C [134].

Tricyclazole (announced in 1976) is used as a seedling box treatment and as a foliar spray for the control of rice blast. The mode of action is considered to be by the inhibition of melanin synthesis. The lack of melanin prevents the fungus from penetrating the leaf.

Trade Names. Beam (Dow Elanco); Sezola (Sananda).

Ethirimol [*23947-60-6*], 5-butyl-2-ethylamino-6-methylpyrimidin-4-ol, $C_{11}H_{19}N_3O$, M_r 209.3, *mp* 159 – 160 °C, vapor pressure 267 µPa at 25 °C, consists of colorless crystals which are practically insoluble in water, slightly soluble in ethanol, and soluble in chloroform or trichloroethylene [9, p. 245], [14, p. 211].

Ethirimol is produced by reaction of ethyl 2-butylacetoacetate and *N*-ethylguanidine [135].

Ethirimol (announced in 1969) is used as a foliar spray and seed treatment. It has protective and curative activity but only against powdery mildew. It is used on cucurbits and cereals. Resistant strains have been detected in field populations of powdery mildew affecting both these crops. The mode of action is by interference with purine metabolism [16, pp. 185 – 205].
Trade Name. Milgo (Zeneca).

Bupirimate [*41483-43-6*], 5-butyl-2-ethylamino-6-methylpyrimidin-4-yl dimethylsulfamate, $C_{13}H_{24}N_4O_3S$, M_r 316.4, *mp* 50 – 51 °C, vapor pressure 67 µPa at 20 °C, is a pale-tan, waxy solid which is slightly soluble in water but soluble in most organic solvents [9, p. 70].

Bupirimate is produced by refluxing the sodium salt of 2-ethylamino-4-methyl-5-butyl-6-hydroxypyrimidine with dimethylsulfamoyl chloride in toluene [136].

Bupirimate (announced in 1975) is used as a foliar fungicide for the control of powdery mildew of apple and ornamentals. It has both protective and curative properties; its mode of action is the same as that of ethirimol.
Trade Name. Nimrod (Zeneca).

Probenazole [*27605-76-1*], 3-(2-propenyloxy)-1,2-benzisothiazole 1,1-dioxide, $C_{10}H_9NO_3S$, M_r 223.24, *mp* 128 – 129 °C, consists of colorless crystals which are slightly soluble in water, readily soluble in most common organic solvents [29, p. 821].

Probenazole is produced by reaction of 3-chloro-1,2-benzoisothiazole 1,1-dioxide with allyl alcohol [137].

Probenazole (announced in 1977) is used in granular form as an "into-water treatment" to control blast and bacterial leaf blight of rice. The compound is effective only when administered via the root system. It has little activity against the target pathogens in vitro and confers protection by the induction of host resistance mechanisms [138].
Trade Name. Oryzemate (Meiji Seika, Hokko).

Carpropamid [*104030-54-8*], 2,2-dichloro-*N*-[1-(4-chlorophenyl)ethyl]-1-ethyl-3-methylcyclopropanecarboxamide, $C_{15}H_{18}Cl_3NO$, M_r 334.7, *mp* 145-149 °C, is a colorless powder which is sparingly soluble in water [22, p. 744].

Carpropamid is produced by reaction of 1-ethyl-2,2-dichloro-3-methylcyclopropanecarboxylic acid chloride with 4-chloro-α-methylbenzylamine in toluene in the presence of triethylamine [139].

Carpropamid (announced in 1994) acts specifically against *Pyricularia oryzate*; it does not provide curative properties, so protective treatment is essential. It is also used for seed treatment.
Trade Names. Win, Win Admire, Arcado (Bayer); Seed One, Zabara (Hannona).

Spiroxamine [*118134-30-8*], 8-*tert*-butyl-1,4-dioxaspiro[4,5]decan-2-ylmethyl(ethyl)(propyl)amine, $C_{18}H_{35}NO_2$, M_r 297.5, is a yellowish liquid which is fairly soluble in water (pH 3) [22, p. 746].

Spiroxamine is produced by ketalization of 4-*tert*-butylcyclohexanone with 1-chloro-2,3-dihydroxypropane, followed by treatment with ethylpropylamine [140].

Spiroxamine (announced in1996) is a new sterol biosynthesis inhibitor acting mainly by inhibition of Δ^{14} reductase. Intended for use as

a sytemic foliar fungicide in wheat and barley, with rapid initial effect and prolonged activity.
Trade Names. To be announced (Bayer).

Fenpropidin [*67306-00-7*], (*RS*)-1-[3-(4-*tert*-butylphenyl)-2-methylpropyl]piperidine, $C_{19}H_{31}N$, M_r 273.5, *bp* >250 °C, is a pale yellow, slightly viscous liquid which is slightly soluble in water but completely miscible with acetone, ethanol, toluene, *n*-octanol, and *n*-heptane [22, p. 526].

Fenpropidin is produced by condensation of 4-*tert*-butylbenzaldehyde with propanal to give 4-*tert*-butylphenyl-2-methylpropylinealdehyde, the hydrogenation product of which is condensed with piperidine, followed by hydrogenation [141].

Fenpropidin (announced in 1986) is used to control powdery mildew, rusts, and *Rhynchosporium secalis* in barley and wheat.
Trade Names. Term (Novartis); Columbia (Zeneca); Sponsor (AgrEvo).

Famoxadone [*131807-57-3*], 3-anilino-5-methyl-5-(4-phenoxyphenyl)-1,3-oxazolidine-2,4-dione, $C_{22}H_{18}N_2O_4$, M_r 374.4, *mp* 140.3 – 141.8 °C, is practically insoluble in water [22, p. 500].

Famoxadone is produced by reaction of 2-(4-phenoxyphenyl)lactate with a mixture of phenoxyphenyl and 1,1′-carbonyldiimidazole in dichloromethane, followed by treatment with phenylhydrazine [142].

Famoxadone (announced in 1996) inhibits mitochondrial electron transport by blocking ubiquinone:cytochrome c oxidoreductase at complex III. It is used to control a broad spectrum of fungi, being particularly effective against grape downy mildew, potato and tomato late and early blights, wheat leaf and glume blotch, and barley net blotch.
Trade Name. To be announced (Du Pont).

Quinoxyfen [*124495-18-7*], 5,7-dichloro-4-quinolyl-4-fluorophenyl ether, $C_{15}H_8Cl_2FNO$, M_r 308.1, [22, p. 1083].

Quinoxyfen is produced by reaction of 4,5,7-trichloroquinoline with *p*-fluorophenol in the presence of 4-dimethylaminopyridine as catalyst in refluxing xylene [143].

Quinoxyfen (announced in 1996) is used to control cereal powdery mildew and offers long-term protection.
Trade Name. To be announced (Dow Elanco).

Table 1. World fungicide market in 1987 [144]

Type of fungicide	Share of world sales∗, %
Nonsystemic fungicides	
Dithiocarbamates	11.2
Inorganics	7.6
Others	12.2
Total nonsystemics	31.0
Systemic fungicides	
Benzimidazoles	6.7
Organophosphates	3.3
Triazoles	23.9
Substituted anilides	11.0
Morpholines	4.8
Strobilurins	3.7
Others	15.6
Total systemics	69.0

∗ Total world sales = $ 5515 × 10^6

9. Economic Aspects

In 1997, fungicides accounted for 18 % of the world market for agrochemicals with an end user value of $ 5515 × 10^6. Fungicide sales were highest in value in Western Europe (43 %), followed by Japan (19 %), North America (14 %), and Latin America (12 %).

Fruit and vegetables accounted for the largest share (47 %) in terms of value of the fungicide market in 1997. This was followed by cereals (25 %) and rice (13.6 %) (→ Crop Protection,

Chap. 3.). Distribution of market shares between the different types of fungicides is shown in Table 1.

10. Toxicology and Occupational Health

A summary of the toxicology of nonsystemic fungicides, fungicidal antibiotics, and systemic fungicides currently in use is given below. Because most of these compounds are proprietary products, many of the toxicological data are not published. Information published in monographs by WHO/FAO was given preference over unreferenced data in handbooks, because the original data were available to the experts of the WHO/FAO panels and the monographs are fully referenced. Furthermore the data of the corresponding studies were conducted according to internationally accepted test protocols and good laboratory practice.

10.1. Nonsystemic (Contact) Fungicides

10.1.1. Inorganic Compounds

Sulfur [*7704-34-9*] has a low toxicity; colloidal sulfur is more toxic than crystalline or powdered sulfur. Irritation of the skin and mucous membranes occurs in persons sensitive to it. In guinea pigs, enzymes were affected only after oral administration of very high dosages for more than 60 d [145], [146]. Sulfur is partly converted to hydrogen sulfide, some of which enters the general metabolic pool. Acute inhibition of cellular respiration by inactivation of enzymes containing heavy metals was observed only at very high doses; this effect is therefore of no significance when sulfur is used as a fungicide.

LD_{50} (mouse, oral)	209 – 245	mg/kg	[22, p. 1193]
LC_{50} (rat, 4-h inhalation)	0.06	mg/L air	[22, p. 1193]
Chronic (rat, 2-year feed)	0.01	$mg\,kg^{-1}\,d^{-1}$	[22, p. 1193]

Copper [*7440-50-8*]. Copper compounds were first employed as a fungicide in the form of bordeaux mixture in the late 1800s. The acute toxicity of the mixture is low. Generally the copper compounds used as fungicides owe their mammalian toxicity to a high overdose of copper ions, in particular copper(II) ion. In high doses, it leads to gastrointestinal disorders [147]. Poisoning due to long-term exposure to copper fungicides, on the average for 18 years, has been described. A specific lung condition produced after long periods of exposure (3 – 15 years) to copper sulfate is known as vineyard sprayer lung. Such an effect has not been described for copper oxychloride [148], [149].

Copper(II) Oxychloride [*1332-40-7*]

LD_{50} (rat, oral)	700 – 800	mg/kg	[22, p. 269]
LD_{50} (rat, dermal)	>2000	mg/kg	[22, p. 269]
LC_{50} (rat, 4-h inhalation)	>30	mg/L air	[22, p. 269]

Copper(I) Oxide [*1317-39-1*]

LD_{50} (rat, oral)	470	mg/kg	[22, p. 277]
LD_{50} (rat, dermal)	>2000	mg/kg	[22, p. 277]

10.1.2. Organometallic Compounds

Organomercury fungicides are no longer used in agriculture because of their toxicity; only organotin compounds are worth mentioning.

Fentin Hydroxide [*76-87-9*]

LD_{50} (rat, oral)	110 – 171	mg/kg	[150]
LD_{50} (dog, oral)	100	mg/kg	[150]
LD_{50} (rat, dermal)	1600	mg/kg	[150]
LD_{50} (rabbit, dermal)	127	mg/kg	[150]
LC_{50} (rat, 4-h inhalation)	0.06	mg/L air	[150]

Rabbit: slightly irritating to skin [150]
Rabbit: severely irritating to eyes [150]
Guinea pig: not a skin sensitizer [150]
Nonmutagenic [150]
NOEL/NOAEL:

Reproduction.			
Rat (2-generation feed):	0.4	$mg\,kg^{-1}\,d^{-1}$ (parental and developmental)	[150]
Teratogenicity.			
Rat (gavage)	1	$mg\,kg^{-1}\,d^{-1}$ (maternal)	[150]
	2.8	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[150]
Rabbit (gavage):	0.1	$mg\,kg^{-1}\,d^{-1}$ (maternal)	[150]
	0.3	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[150]

Chronic.

Rat (2-year feed):	< 0.3	$mg\,kg^{-1}\,d^{-1}$	[150]
Mouse (18-month feed):	1	$mg\,kg^{-1}\,d^{-1}$	[150]
Dog (one-year feed):	0.2	$mg\,kg^{-1}\,d^{-1}$	[150]

ADI: $0.0005\,mg\,kg^{-1}\,d^{-1}$ [150]

Ingestion of Fentin hydroxide by humans causes gastrointestinal disorders. After several hours or even days, headache, giddiness, vomiting, and abdominal pain occur. In serious cases, paralysis, cerebral edema, and ocular changes result [150].

10.1.3. Dithiocarbamates

In general, the acute and dermal toxicity of dithiocarbamate fungicides is low. The chronic toxicity of dithiocarbamates is related to a common metabolite of ethylenebisthiocarbamates, namely, ethylene thiourea (ETU) [*96-45-7*]. It is formed in plants and animals, and in food during processing and cooking. It is carcinogenic in animals, inducing thyroid tumors (follicular adenomas and carcinomas) and liver tumors. Thyroid neoplasia appears to be related to a nongenotoxic, epigenetic mechanism involving inhibition of thyroid peroxidase, a common effect of dithiocarbamates in rats [151].

ETU [*96-45-7*]

LD_{50} (rat, oral)	940 – 2400	mg/kg	[152]
LD_{50} (mouse, oral)	4000	mg/kg	[152]
LD_{50} (hamster)	> 3000	mg/kg	[152]

Nonmutagenic [152]
NOEL/NOAEL:
Reproduction.

Rat (2-generation feed):	0.16 – 0.38	$mg\,kg^{-1}\,d^{-1}$	[152]

Teratogenicity.

Rat (gavage)	40	$mg\,kg^{-1}\,d^{-1}$ (maternal)	[152]
	5	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[152]
Rabbit (gavage):	80	$mg\,kg^{-1}\,d^{-1}$ (maternal)	[152]
	40	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[152]

Chronic.

Rat (2-year feed):	0.37	$mg\,kg^{-1}\,d^{-1}$	[152]
Mouse (3-month feed):	1.7	$mg\,kg^{-1}\,d^{-1}$	[152]
Dog (one-year feed):	0.18	$mg\,kg^{-1}\,d^{-1}$	[152]

ADI: $0.004\,mg\,kg^{-1}\,d^{-1}$ [152]

Ferbam [*14484-64-1*]

LD_{50} (rat, oral)	> 4000	mg/kg	[153]
LD_{50} (mouse, oral)	1000	mg/kg	[153]
LD_{50} (guinea pig, oral)	450 – 2000	mg/kg	[153]
LD_{50} (rabbit, oral)	2000 – 3000	mg/kg	[154, p. 460]

Rabbit: irritating to skin and eyes [153]
Nonmutagenic [153]
NOEL/NOAEL:
Chronic.

Rat (2-year feed):	12.5	$mg\,kg^{-1}\,d^{-1}$	[155]
Dog (2-year feed):	5	$mg\,kg^{-1}\,d^{-1}$	[155]

ADI: $0.02\,mg\,kg^{-1}\,d^{-1}$ [154, p. 460]

Mancozeb [*8018-01-7*]

LD_{50} (rat, oral)	> 5000	mg/kg	[152, p. 167]
LD_{50} (mouse, oral)	> 5000	mg/kg	[152, p. 167]

Dog (one-year capsule):	5	$mg\,kg^{-1}\,d^{-1}$	[154, p. 1050]

ADI: 0.02 $mg\,kg^{-1}\,d^{-1}$ [154, p. 1050]

10.1.4. *N*-Trihalomethylthio Derivatives (Phthalimides)

The acute oral and dermal toxicity of *N*-trihalomethylthio fungicides is low. Controversy continues regarding their mutagenic and teratogenic effects. Sperm mobility was inhibited in rats and mice after intake for longer periods. Particular attention has been paid to the teratogenic effects of *N*-trihalomethylthio derivatives because of their close structural relationship to thalidomide. Captan, folpet, and their primary metabolites did not produce teratogenic changes in rabbits. In chronic feeding experiments with captan in mice, tumor formation was reported in the small intestine. This could be because the compound is probably metabolized in the gastrointestinal tract. High dosages inhibit mitochondrial respiration in isolated liver cells; lower doses cause oxidative uncoupling.

Captafol [*2425-06-1*]

LD_{50} (rat, oral)	2500 – 6200	mg/kg	[157]
LD_{50} (rabbit, dermal)	> 15 000	mg/kg	[157]

Nonmutagenic [158]
NOEL/NOAEL:
Chronic.

Rat (2-year feed):	12.5	$mg\,kg^{-1}\,d^{-1}$	[158]
Dog (one-year capsule):	10	$mg\,kg^{-1}\,d^{-1}$	[158]

Captan [*133-06-2*]

LD_{50} (rat, oral)	2650	mg/kg	[159]

Reproduction.

Rat (3-generation feed):	75	$mg\,kg^{-1}\,d^{-1}$ (parental and developmental)	[161]

Teratogenicity.

Rabbit (gavage):	30	$mg\,kg^{-1}\,d^{-1}$ (maternal and developmental)	[162]

Chronic.

Rat (2-year feed):	30	$mg\,kg^{-1}\,d^{-1}$	[162]
Mouse (2-year feed):	252	$mg\,kg^{-1}\,d^{-1}$	[162]
Dog (2-year feed):	25	$mg\,kg^{-1}\,d^{-1}$	[162]

ADI: 0.3 $mg\,kg^{-1}\,d^{-1}$ [162]

Folpet [*133-07-3*]

LD_{50} (rat, oral)	> 5000	mg/kg	[160, p. 127]
LD_{50} (rabbit, dermal)	> 23 000	mg/kg	[160, p. 127]
LC_{50} (rat, 4-h inhalation)	0.39	mg/L air	[160, p. 127]

Guinea pig: irritating to skin [160, p. 127]
Guinea pig: a skin sensitizer [160, p. 127]
Nonmutagenic (in vivo) [160, p. 127]

NOEL/NOAEL:
Reproduction.

Rat (2-generation feed):	13.7	$mg\,kg^{-1}\,d^{-1}$ (parental and developmental)	[163]

Teratogenicity.

Rat (gavage):	10	$mg\,kg^{-1}\,d^{-1}$ (maternal and developmental)	[160, p. 127]

Chronic.

Rat (2-year feed):	9.5	$mg\,kg^{-1}\,d^{-1}$	[163]
Mouse (2-year feed):	16	$mg\,kg^{-1}\,d^{-1}$	[160, p. 127]
Dog (one-year feed):	10	$mg\,kg^{-1}\,d^{-1}$	[160, p. 127]

ADI: 0.1 $mg\,kg^{-1}\,d^{-1}$ [160, p. 127]

Tolylfluanid [*731-27-1*]

LD_{50} (rat, oral)	> 5000	mg/kg	[164]
LD_{50} (mouse, oral)	> 1000	mg/kg	[164]
LD_{50} (rabbit, oral)	> 1000	mg/kg	[164]
LD_{50} (rat, dermal)	> 5000	mg/kg	[164]

Rabbit: nonirritating to skin [164]
Rabbit: irritating to eyes [164]
Guinea pig: a skin sensitizer [164]
Nonmutagenic (in vivo) [164]
NOEL/NOAEL:
Reproduction.

Rat (2-generation feed):	15	$mg\,kg^{-1}\,d^{-1}$ (parental and developmental)	[164]

Teratogenicity.

Rat (gavage):	100	$mg\,kg^{-1}\,d^{-1}$ (maternal and developmental)	[164]

Chronic.

Rat (2-year feed):	15	$mg\,kg^{-1}\,d^{-1}$	[164]
Mouse (2-year feed):	714	$mg\,kg^{-1}\,d^{-1}$	[164]
Dog (one-year capsule):	12.5	$mg\,kg^{-1}\,d^{-1}$	[164]

ADI: 0.1 $mg\,kg^{-1}\,d^{-1}$ [164]

10.1.5. Dicarboximides

Dicarboximides do not have a very high acute oral or dermal toxicity in rats, rabbits, and some species of wildlife. In animal experiments, apathy and respiratory disturbances predominate; dogs undergo a temporary loss of appetite.

Chlozolinate [*84332-86-5*]

LD_{50} (rat, oral)	> 4500	mg/kg	[154, p. 208]
LD_{50} (mouse, oral)	> 10 000	mg/kg	[154, p. 208]
LD_{50} (rat, dermal)	> 5000	mg/kg	[154, p. 208]
LC_{50} (rat, 4-h inhalation)	> 10	mg/L air	[154, p. 208]

Rabbit: nonirritating to skin and eyes [154, p. 208]
Guinea pig: a skin sensitizer [154, p. 208]

Iprodione [*36734-19-7*]

LD_{50} (rat, oral)	> 2000	mg/kg	[156, p. 211]
LD_{50} (mouse, oral)	1870 – 2670	mg/kg	[156, p. 211]
LD_{50} (dog, oral)	> 2000	mg/kg	[156, p. 211]
LD_{50} (rabbit, dermal)	> 2000	mg/kg	[156, p. 211]
LC_{50} (rat, 4-h inhalation)	> 3.3	mg/L air	[156, p. 211]

Rabbit: mildly irritating to eyes [156, p. 211]
Rabbit: nonirritating to skin [156, p. 211]
Guinea pig: not a skin sensitizer [156, p. 211]
Nonmutagenic [156, p. 211]
NOEL/NOAEL:
Reproduction.

Rat (2-generation feed):	21	$mg\,kg^{-1}\,d^{-1}$ (parental)	[156, p. 211]
	71	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[156, p. 211]

Teratogenicity.

Rat (gavage):	200	$mg\,kg^{-1}\,d^{-1}$ (maternal)	[156, p. 211]
	90	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[156, p. 211]
Rabbit (gavage):	20	$mg\,kg^{-1}\,d^{-1}$ (maternal)	[156, p. 211]
	60	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[156, p. 211]

Chronic.

Rat (2-year feed):	12.5	$mg\,kg^{-1}\,d^{-1}$	[156, p. 211]
Dog (one-year feed):	18	$mg\,kg^{-1}\,d^{-1}$	[156, p. 211]

ADI: 0.2 $mg\,kg^{-1}\,d^{-1}$ [156, p. 211]

Procymidone [*32809-16-8*]

LD_{50} (rat, oral)	> 5000	mg/kg	[165]
LD_{50} (mouse, oral)	> 5000	mg/kg	[165]
LD_{50} (rat, dermal)	> 5000	mg/kg	[165]
LD_{50} (mouse, dermal)	> 5000	mg/kg	[165]
LC_{50} (rat, 4-h inhalation)	> 1.5	mg/L air	[165]

Rabbit: nonirritating to skin and eyes [165]
Guinea pig: not a skin sensitizer [165]
Nonmutagenic [165]
NOEL/NOAEL:
Reproduction.

Rat (2-generation feed):	2.5	$mg\,kg^{-1}\,d^{-1}$ (parental and developmental)	[165]

Teratogenicity.

Rat (gavage):	300	$mg\,kg^{-1}\,d^{-1}$ (maternal and developmental)	[165]
Rabbit (gavage):	750	$mg\,kg^{-1}\,d^{-1}$ (maternal and developmental)	[165]

Chronic.

Rat (2-year feed):	4.6	$mg\,kg^{-1}\,d^{-1}$	[165]
Mouse (2-year feed):	14.3	$mg\,kg^{-1}\,d^{-1}$	[165]
Dog (6-month capsule):	100	$mg\,kg^{-1}\,d^{-1}$	[165]

ADI: 0.2 $mg\,kg^{-1}\,d^{-1}$ [165]

Vinclozolin [*50471-44-8*]

LD_{50} (rat, oral)	> 15 000	mg/kg	[160, p. 181]
LD_{50} (mouse, oral)	> 15 000	mg/kg	[160, p. 181]
LD_{50} (guinea pig, oral)	8000	mg/kg	[160, p. 181]
LD_{50} (rat, dermal)	> 5000	mg/kg	[160, p. 181]
LC_{50} (rat, 4-h inhalation)	> 29.1	mg/L air	[160, p. 181]

Rabbit: nonirritating to skin and eyes [160, p. 181]
Guinea pig: a skin sensitizer [160, p. 181]
Nonmutagenic [160, p. 181]
NOEL/NOAEL:
Reproduction.

Rat (2-generation feed):	4	$mg\,kg^{-1}\,d^{-1}$ (parental)	[160, p. 181]
	15	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[160, p. 181]
Teratogenicity.			
Rat (gavage):	400	$mg\,kg^{-1}\,d^{-1}$ (maternal)	[160, p. 181]
	100	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[160, p. 181]
Rabbit (gavage):	50	$mg\,kg^{-1}\,d^{-1}$ (maternal)	[160, p. 181]
	200	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[160, p. 181]
Chronic.			
Rat (2-year feed):	1.4	$mg\,kg^{-1}\,d^{-1}$	[160, p. 181]
Mouse (18-month feed):	24	$mg\,kg^{-1}\,d^{-1}$	[160, p. 181]
Dog (one-year feed):	2.4	$mg\,kg^{-1}\,d^{-1}$	[160, p. 181]

ADI: 0.01 $mg\,kg^{-1}\,d^{-1}$ [160, p. 181]

10.1.6. Miscellaneous Organic Compounds

Biphenyl [*92-52-4*]

LD_{50} (rat, oral)	2410	mg/kg	[157, p. 1433]
LD_{50} (rabbit, oral)	3280	mg/kg	[157, p. 1433]

Rabbit: nonirritating to skin [157, p. 1433]
NOEL/NOAEL:
Reproduction.

Rat (3-generation feed):	50	$mg\,kg^{-1}\,d^{-1}$ (parental and developmental)	[157, p. 1433]
Chronic.			
Rat (2-year feed):	25	$mg\,kg^{-1}\,d^{-1}$	[157, p. 1433]
Dog (one-year feed):	20	$mg\,kg^{-1}\,d^{-1}$	[157, p. 1433]
Monkey (one-year feed):	20	$mg\,kg^{-1}\,d^{-1}$	[157, p. 1433]

ADI: 0.125 $mg\,kg^{-1}\,d^{-1}$ [154, p. 105]

Chlorothalonil [*1897-45-6*]

LD_{50} (rat, oral)	10 000	mg/kg	[163, p. 101]
LD_{50} (dog, oral)	> 5000	mg/kg	[163, p. 101]
LD_{50} (rabbit, dermal)	10 000	mg/kg	[163, p. 101]
LC_{50} (rat, 4-h inhalation)	0.6	mg/L air	[154, p. 193]

Rabbit: mildly irritating to skin [154, p. 193]
Rabbit: severely irritating to eyes [154, p. 193]
Nonmutagenic [156, p. 103]
Nonteratogenic [156, p. 103]
NOEL/NOAEL:
Reproduction.

Rat (2-generation feed):	75	$mg\,kg^{-1}\,d^{-1}$ (parental)	[156, p. 103]
Chronic.			
Rat (2-year feed):	1.5	$mg\,kg^{-1}\,d^{-1}$	[156, p. 103]
Mouse (2-year feed):	1.6	$mg\,kg^{-1}\,d^{-1}$	[156, p. 103]
Dog (2-year feed):	3.0	$mg\,kg^{-1}\,d^{-1}$	[156, p. 103]

ADI: 0.03 $mg\,kg^{-1}\,d^{-1}$ [156, p. 103]

Diphenylamine [*122-39-6*]

LD_{50} (rat, oral)	3280	mg/kg	[157, p.1433]
LD_{50} (rabbit, oral)	2410	mg/kg	[157, p.1433]

NOEL/NOAEL:
Reproduction.

Rat (3-generation feed):	50	$mg\,kg^{-1}\,d^{-1}$	[157, p. 1433]
Chronic.			
Rat (2-year feed):	25	$mg\,kg^{-1}\,d^{-1}$	[157, p. 1433]
Mouse (80-week feed):	15	$mg\,kg^{-1}\,d^{-1}$	[166]
Dog (one-year feed):	> 20	$mg\,kg^{-1}\,d^{-1}$	[157, p. 1433]
Monkey (one-year feed):	20	$mg\,kg^{-1}\,d^{-1}$	[157, p. 1433]

ADI: 0.025 $mg\,kg^{-1}\,d^{-1}$ [166]

2-Phenylphenol [*90-43-7*]

LD_{50} (rat, oral)	2700	mg/kg	[154, p. 794]
LD_{50} (mouse, oral)	2000	mg/kg	[154, p. 794]

Rabbit: mildly irritating to skin [154, p. 794]
Nonmutagenic [167]
NOEL/NOAEL:
Reproduction.

Rat (2-generation gavage):	40	$mg\,kg^{-1}\,d^{-1}$ (parental)	[167]
	49	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[167]
Teratogenicity.			
Rat (gavage):	150	$mg\,kg^{-1}\,d^{-1}$ (maternal)	[167]
	300	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[167]

Chronic.

Rat (2-year feed):	2	$mg\,kg^{-1}\,d^{-1}$	[167]
Dog (one-year gavage):	300	$mg\,kg^{-1}\,d^{-1}$	[167]

ADI: $0.02\,mg\,kg^{-1}\,d^{-1}$ [167]

Quintozene [*82-68-8*]

LD_{50} (rat, oral)	> 1500	mg/kg	[160, p. 173]
LD_{50} (dog, oral)	> 1500	mg/kg	[160, p. 173]
LD_{50} (rabbit, dermal)	> 5000	mg/kg	[160, p. 173]
LC_{50} (rat, 4-h inhalation)	> 1.7	mg/L air	[160, p. 173]

Rabbit: nonirritating to skin [160, p. 173]
Rabbit: mildly irritating to eyes [160, p. 173]
Guinea pig: a mild skin sensitizer [160, p. 173]
Human, a mild skin sensitizer [160, p. 173]
NOEL/NOAEL:
Reproduction.

Rat (2-generation feed):	1	$mg\,kg^{-1}\,d^{-1}$ (parental and developmental)	[160, p. 173]

Teratogenicity.

Rat (gavage):	> 1200	$mg\,kg^{-1}\,d^{-1}$ (maternal and developmental)	[160, p. 173]
Rabbit (gavage):	12	$mg\,kg^{-1}\,d^{-1}$ (maternal)	[160, p. 173]
	120	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[160, p. 173]

Chronic.

Rat (2-year feed):	1	$mg\,kg^{-1}\,d^{-1}$	[160, p. 173]
Mouse (103-week feed):	390	$mg\,kg^{-1}\,d^{-1}$	[160, p. 173]
Dog (one-year feed):	4.2	$mg\,kg^{-1}\,d^{-1}$	[160, p. 173]

ADI: $0.01\,mg\,kg^{-1}\,d^{-1}$ [160, p. 173]

sec-Butylamine [*13952-84-6*]

LD_{50} (rat, oral)	350	mg/kg	[168]
LD_{50} (mouse, oral)	660	mg/kg	[168]
LD_{50} (dog, oral)	250	mg/kg	[168]
LD_{50} (rabbit, dermal)	2500	mg/kg	[168]
LC_{50} (rat, 4-h inhalation)	3.5	mg/L air	[168]

Rabbit: irritating to skin [168]
NOEL/NOAEL:
Chronic.

Rat (2-year feed):	35	$mg\,kg^{-1}\,d^{-1}$	[168]
Dog (2-year capsule):	69	$mg\,kg^{-1}\,d^{-1}$	[168]

ADI: $0.2\,mg\,kg^{-1}\,d^{-1}$ [168]

Chinomethionat [*2439-01-2*]

LD_{50} (rat, oral)	> 1000	mg/kg	[158, p. 63]
LD_{50} (rat, dermal)	> 2000	mg/kg	[158, p. 63]
LC_{50} (rat, 4-h inhalation)	3	mg/L air	[154, p. 163]

Rabbit: slightly irritating to skin and eyes [154, p. 163]
Nonmutagenic [169]
NOEL/NOAEL:
Reproduction.

Rat (2-generation feed):	0.75	$mg\,kg^{-1}\,d^{-1}$ (parental and developmental)	[169]

Teratogenicity.

Rat (gavage):	25	$mg\,kg^{-1}\,d^{-1}$ (maternal and developmental)	[169]
Rabbit (gavage):	30	$mg\,kg^{-1}\,d^{-1}$ (maternal and developmental)	[169]

Chronic.

Rat (2-year feed):	0.6	$mg\,kg^{-1}\,d^{-1}$	[169]
Mouse (21-month feed):	16	$mg\,kg^{-1}\,d^{-1}$	[169]
Dog (one-year feed):	0.6	$mg\,kg^{-1}\,d^{-1}$	[169]

ADI: $0.006\,mg\,kg^{-1}\,d^{-1}$ [169]

Cymoxanil [*57966-95-7*]

LD_{50} (rat, oral)	1196 – 1390	mg/kg	[154, p. 257]
LD_{50} (guinea pig, oral)	1096	mg/kg	[154, p. 257]
LD_{50} (rabbit, dermal)	> 3000	mg/kg	[154, p. 257]
LD_{50} (dog, dermal)	> 3000	mg/kg	[154, p. 257]
LC_{50} (rat, 4-h inhalation)	> 5.06	mg/L air	[154, p. 257]

Rabbit: mildly irritating to eyes [154, p. 257]
Rabbit: nonirritating to skin [154, p. 257]
Guinea pig: not a skin sensitizer [154, p. 257]
NOEL/NOAEL:
Chronic.

Rat (2-year feed):	5	$mg\,kg^{-1}\,d^{-1}$	[154, p. 257]

Dichlorophen [*97-23-4*]

LD_{50} (rat, oral)	2690	mg/kg	[154, p. 306]
LD_{50} (mouse, oral)	1000	mg/kg	[154, p. 306]
LD_{50} (guinea pig, oral)	1250	mg/kg	[154, p. 306]
LD_{50} (dog, oral)	2000	mg/kg	[154, p. 306]

NOEL/NOAEL:
Subchronic.

Rat (90-day feed):	133	$mg\,kg^{-1}\,d^{-1}$	[154, p.]306

Diclomezine [*62865-36-5*]

LD_{50} (rat, oral)	> 12 000	mg/kg	[154, p. 317]
LD_{50} (rat, dermal)	> 5000	mg/kg	[154, p. 317]
LC_{50} (rat, 4-h inhalation)	0.82	mg/L air	[154, p. 317]

Rabbit: nonirritating to skin [154, p. 317]
Nonmutagenic [154, p. 317]
Nonteratogenic [154, p. 317]

Dicloran [*99-30-9*]

LD_{50} (rat, oral)	4000 – 10 000	mg/kg	[170]
LD_{50} (mouse, oral)	1500 – 2500	mg/kg	[170]
LD_{50} (cat, oral)	> 500	mg/kg	[170]
LD_{50} (guinea pig, oral)	1450	mg/kg	[170]
LD_{50} (mouse, dermal)	> 5000	mg/kg	[170]
LD_{50} (rabbit, dermal)	> 2000	mg/kg	[154, p. 318]
LC_{50} (rat, one-h inhalation)	> 21.6	mg/L air	[154, p. 318]

Rabbit: nonirritating to skin and eyes [154, p. 318]
Guinea pig: not a skin sensitizer [154, p. 318]
Nonmutagenic [158, p. 39]
NOEL/NOAEL:
Reproduction.

Rat (2-generation feed):	25	$mg\,kg^{-1}\,d^{-1}$ (parental and developmental)	[158, p. 39]
Chronic.			
Rat (2-year feed):	50	$mg\,kg^{-1}\,d^{-1}$	[158, p. 39]
Dog (2-year feed):	2.5	$mg\,kg^{-1}\,d^{-1}$	[154, p. 39]

ADI: 0.03 $mg\,kg^{-1}\,d^{-1}$ [158, p. 39]

Dithianon [*3347-22-6*]

LD_{50} (rat, oral)	678 – 720	mg/kg	[156, p. 165]
LD_{50} (mouse, oral)	492 – 528	mg/kg	[156, p. 165]
LD_{50} (rat, dermal)	> 2000	mg/kg	[156, p. 165]
LD_{50} (mouse, dermal)	> 3200	mg/kg	[156, p. 165]
LC_{50} (rat, 4-h inhalation)	2.1	mg/L air	[156, p. 165]

Rabbit: nonirritating to skin [156, p. 165]
Rabbit: severely irritating to eyes [156, p. 165]
Guinea pig: not a skin sensitizer [156, p. 165]
Nonmutagenic [156, p. 165]
NOEL/NOAEL:
Reproduction.

Rat (2-generation feed):	10	$mg\,kg^{-1}\,d^{-1}$ (parental)	[156, p. 165]
Teratogenicity.			
Rat (gavage):	20	$mg\,kg^{-1}\,d^{-1}$ (maternal and developmental)	[156, p. 165]
Rabbit (gavage):	10	$mg\,kg^{-1}\,d^{-1}$ (maternal)	[156, p. 165]
	25	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[157, p. 165]
Chronic.			
Rat (2-year feed):	1	$mg\,kg^{-1}\,d^{-1}$	[156, p. 165]
Mouse (80-week feed):	2.9	$mg\,kg^{-1}\,d^{-1}$	[156, p. 165]
Dog (2-year feed):	1	$mg\,kg^{-1}\,d^{-1}$	[156, p. 165]

ADI: 0.01 $mg\,kg^{-1}\,d^{-1}$ [156, p. 165]

Dodine [*2439-10-3*]

LD_{50} (rat, oral)	750 – 1540	mg/kg	[161, p. 265]
LD_{50} (rabbit, oral)	535	mg/kg	[161, p. 265]
LD_{50} (guinea pig, oral)	176	mg/kg	[161, p. 265]
LD_{50} (rabbit, dermal)	2100 – 10 000	mg/kg	[161, p. 265]

Rabbit: severely irritating to skin and eyes [161, p. 265]
NOEL/NOAEL:
Reproduction.

Rat (2-generation feed):	< 40	$mg\,kg^{-1}\,d^{-1}$ (parental)	[161, p. 265]
	> 40	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[161, p. 265]
Chronic.			
Rat (2-year feed):	10	$mg\,kg^{-1}\,d^{-1}$	[161, p. 265]
Dog (one-year feed):	1.25	$mg\,kg^{-1}\,d^{-1}$	[161, p. 265]

ADI: 0.01 $mg\,kg^{-1}\,d^{-1}$ [161, p. 265]

Etridiazole [*2593-15-9*]

LD_{50} (rat, oral)	1028	mg/kg	[154, p. 419]
LD_{50} (mouse, oral)	2000	mg/kg	[154, p. 419]
LD_{50} (rabbit, oral)	779	mg/kg	[154, p. 419]
LD_{50} (rabbit, dermal)	> 5000	mg/kg	[154, p. 419]
LC_{50} (rat, 4-h inhalation)	> 5.7	mg/L air	[154, p. 419]

Rabbit: nonirritating to skin [154, p. 419]
Rabbit: slightly irritating to eyes [154, p. 419]
NOEL/NOAEL:
Chronic.

Rat (2-year feed):	4	$mg\,kg^{-1}\,d^{-1}$	[154, p. 419]

Dog (one-year feed):	0.25	$mg\,kg^{-1}\,d^{-1}$	[154, p. 1009]

ADI: $0.0005\,mg\,kg^{-1}\,d^{-1}$ [154, p. 1009]

10.2. Fungicidal Antibiotics

Fungicidal antibiotics have a low toxicity. The acute oral LD_{50} of polyoxin B [*19396-06-6*] and validamycin [*37248-47-8*] is reported to be more than 20 000 mg/kg for rats and mice. The acute dermal LD_{50} is also higher than 20 000 mg/kg. In a chronic feeding experiment, the NOEL for polyoxin B was more than 2400 mg/kg/d for rats and > 6800 mg/kg/d for mice [173], [174]. To prevent the development of microbial resistance, antibiotics that are used in human and veterinary medicine should not be employed as agricultural fungicides.

10.3. Systemic Fungicides

10.3.1. Organophosphates

Organophosphates form a complex with cholinesterase that is analogous to the complex formed between the enzyme and its substrate acetylcholine. Enzymatic cleavage of acetylcholine requires only microseconds, and the enzyme is available again almost immediately. However, organic phosphates bind to cholinesterase more strongly than acetylcholine. Depending on the active compound, cleavage may require several days to several weeks.

The inhibitor-enzyme complex can be reactivated by nucleophilic substances within a few hours of its formation; pralidoxime iodide [*94-63-3*] (2-PAM) and obidoxime chloride [*114-90-9*] are the best known antidotes [175], [176]. Atropine, which must be applied in advance, does not affect this blockage but acts on the excess acetylcholine available after degradation of the latter has been prevented [177], [178].

Edifenphos [*17109-49-8*]

LD_{50} (rat, oral)	100 – 340	mg/kg	[179]
LD_{50} (mouse oral)	214	mg/kg	[179]
LD_{50} (guinea pig, oral)	350	mg/kg	[179]
LD_{50} (rabbit, oral)	350	mg/kg	[179]
Nonmutagenic [179]			
NOEL/NOAEL:

Dog (2-year feed):	0.4	$mg\,kg^{-1}\,d^{-1}$	[156, p. 363]
ADI: $0.004\,mg\,kg^{-1}\,d^{-1}$ [156, p. 363]			

10.3.2. Benzimidazoles

Benzimidazoles have moderate to low toxicity. They range from relatively simple compounds to very large molecules with one or more rings containing a nitrogen or a sulfur atom.

In experiments on rats, more than 90 % of a single dose of benomyl or thiophanate is excreted within 72 h via the feces and urine. Methyl-2-benzimidazole carbamate is the primary metabolite of benzimidazoles. They are metabolized by the microsomal hepatic enzymes, as is reflected in liver findings in chronic experiments. No accumulation occurs.

The active fungicide principle is carbendazim.

Benomyl [*17804-35-2*]

LD_{50} (rat, oral)	> 10 000	mg/kg	[162, p. 7]
LD_{50} (rabbit, oral)	> 10 000	mg/kg	[162, p. 7]
LD_{50} (rabbit, dermal)	> 10 000	mg/kg	[162, p. 7]
LC_{50} (rat, 4-h inhalation)	> 4.01	mg/L air	[162, p. 7]

Rabbit: irritating to skin and eyes [162, p. 7]
Guinea pig: a skin sensitizer [162, p. 7]
Nonmutagenic [162, p. 7]
NOEL/NOAEL:
Reproduction.

Rat (2-generation feed):	37	$mg\,kg^{-1}\,d^{-1}$ (parental and developmental)	[160, p. 34]

Teratogenicity.

Dog (2-year gavage):	10	$mg\,kg^{-1}\,d^{-1}$	[160, p. 185]

ADI: 0.02 $mg\,kg^{-1}\,d^{-1}$ [160, p. 185]

10.3.3. Carboxanilides

Carboxin [*5234-68-4*]

LD_{50} (rat, oral)	3820	mg/kg	[154, p. 155]
LD_{50} (rabbit, dermal)	> 4000	mg/kg	[154, p. 155]
LC_{50} (rat, one-h inhalation)	> 20	mg/L air	[154, p. 155]

Rabbit: nonirritating to eyes [154, p. 155]
Guinea pig: not a skin sensitizer [154]
NOEL/NOAEL:
Chronic.

Rat (2-year feed):	30	$mg\,kg^{-1}\,d^{-1}$	[154, p. 155]

ADI: 0.01 $mg\,kg^{-1}\,d^{-1}$ [154, p. 155]

Flutolanil [*66332-96-5*]

LD_{50} (rat, oral)	> 10 000	mg/kg	[154, p. 512]
LD_{50} (rat, dermal)	> 5000	mg/kg	[154, p. 512]
LC_{50} (rat, 4-h inhalation)	> 5.98	mg/L air	[154, p. 512]

Rabbit: nonirritating to skin and eyes [154, p. 512]

Mepronil [*55814-41-0*]

LD_{50} (rat, oral)	> 10 000	mg/kg	[154, p. 656]
LD_{50} (mouse, oral)	> 10 000	mg/kg	[154, p. 656]
LD_{50} (rat, dermal)	> 10 000	mg/kg	[154, p. 656]
LD_{50} (rabbit, dermal)	> 10 000	mg/kg	[154, p. 656]
LC_{50} (rat, 6-h inhalation)	> 1.32	mg/L air	[154, p. 656]

Rabbit: nonirritating to skin and eyes [154, p. 656]
NOEL/NOAEL:
Chronic.

Rat (2-year feed):	0.3	$mg\,kg^{-1}\,d^{-1}$	[154, p. 656]

Thifluzamide [*130000-40-7*]

LD_{50} (rat, oral)	> 5000	mg/kg	[154, p. 978]
LD_{50} (rabbit, dermal)	> 5000	mg/kg	[154, p. 978]

Rabbit: moderately irritating to eyes [154, p. 978]
Rabbit: slightly irritating to skin [154, p. 978]

10.3.4. Phenylamides

Ofurace [*58810-48-3*]

LD_{50} (rat, oral)	2600 – 3500	mg/kg	[154, p. 745]
LD_{50} (rabbit, dermal)	> 5000	mg/kg	[154, p. 745]

Rabbit: severely irritating to eyes [154, p. 745]
Rabbit: mildly irritating to skin [154, p. 745]
Guinea pig: not a skin sensitizer [154, p. 745]
Nonmutagenic (Ames test) [154, p. 745]

Oxadixyl [*77732-09-3*]

LD_{50} (rat, oral)	1860 – 3480	mg/kg	[154, p. 755]
LD_{50} (rat, dermal)	> 2000	mg/kg	[154, p. 755]
LD_{50} (rabbit, dermal)	> 2000	mg/kg	[154, p. 755]
LC_{50} (rat, 6-h inhalation)	> 5.6	mg/L air	[154, p. 755]

Rabbit: nonirritating to skin and eyes [154, p. 755]
Guinea pig: not a skin sensitizer [154, p. 755]
Nonmutagenic [181]
NOEL/NOAEL:
Reproduction.

Rat (3-generation feed):	22	$mg\,kg^{-1}\,d^{-1}$ (parental and developmental)	[181]

Teratogenicity.

Rat (gavage):	250	$mg\,kg^{-1}\,d^{-1}$ (maternal)	[181]
	500	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[181]
Rabbit (gavage):	50	$mg\,kg^{-1}\,d^{-1}$ (maternal)	[181]
	> 200	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[181]

Chronic.

Rat (2-year feed):	10.9	$mg\,kg^{-1}\,d^{-1}$	[181]
Mouse (2-year feed):	15	$mg\,kg^{-1}\,d^{-1}$	[181]
Dog (2-year feed):	> 12.5	$mg\,kg^{-1}\,d^{-1}$	[181]

ADI: 0.11 $mg\,kg^{-1}\,d^{-1}$ [181]

Benalaxyl [*71626-11-4*]

LD_{50} (rat, oral)	4200	mg/kg	[169, p. 9]
LD_{50} (mouse, oral)	680	mg/kg	[169, p. 9]
LD_{50} (rabbit, dermal)	2000	mg/kg	[169, p. 9]
LC_{50} (rat, 4-h inhalation)	> 10	mg/L air	[169, p. 9]

Rabbit: nonirritating to skin and eyes [169, p. 9]
Guinea pig: not a skin sensitizer [169, p. 9]
Nonmutagenic [169, p. 9]

NOEL/NOAEL:
Reproduction.

Rat (2-generation feed):	5	$mg\,kg^{-1}\,d^{-1}$ (parental and developmental)	[169, p. 9]

Teratogenicity.

Rat (gavage):	200	$mg\,kg^{-1}\,d^{-1}$ (maternal and developmental)	[169, p. 9]
Rabbit (gavage):	50	$mg\,kg^{-1}\,d^{-1}$ (maternal)	[169, p. 9]
	5	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[169, p. 9]

Chronic.

Rat (2-year feed):	50	$mg\,kg^{-1}\,d^{-1}$	[169, p. 9]
Mouse (78-week feed):	40	$mg\,kg^{-1}\,d^{-1}$	[169, p. 9]

ADI: $0.05\,mg\,kg^{-1}\,d^{-1}$ [169, p. 9]

Furalaxyl [*57646-30-7*]

LD_{50} (rat, oral)	940	mg/kg	[154, p. 534]
LD_{50} (mouse, oral)	603	mg/kg	[154, p. 534]
LD_{50} (rat, dermal)	>3100	mg/kg	[154, p. 534]
LD_{50} (rabbit, dermal)	5508	mg/kg	[154, p. 534]

Rabbit: mildly irritating to skin and eyes [154, p. 534]
Guinea pig: not a skin sensitizer [154, p. 534]
NOEL/NOAEL:
Subchronic.

Rat (90-day feed):	85	$mg\,kg^{-1}\,d^{-1}$	[154, p. 534]
Dog (90-day feed):	1.8	$mg\,kg^{-1}\,d^{-1}$	[154, p. 534]

ADI: $0.0009\,mg\,kg^{-1}\,d^{-1}$ [154, p. 534]

Metalaxyl [*57837-19-1*]

LD_{50} (rat, oral)	669	mg/kg	[182]
LD_{50} (mouse, oral)	788	mg/kg	[182]
LD_{50} (rabbit, oral)	697	mg/kg	[182]
LD_{50} (hamster, oral)	7170	mg/kg	[182]
LD_{50} (rat, dermal)	>3100	mg/kg	[182]
LD_{50} (rabbit, dermal)	>6000	mg/kg	[182]

Rabbit: mildly irritating to skin and eyes [182]
Guinea pig: not a skin sensitizer [182]
Nonmutagenic [183]
NOEL/NOAEL:
Reproduction.

Rat (3-generation feed):	62.5	$mg\,kg^{-1}\,d^{-1}$ (parental and developmental)	[182]

Teratogenicity.

Rat (gavage):	>120	$mg\,kg^{-1}\,d^{-1}$ (maternal and developmental)	[182]
Rabbit (gavage):	5	$mg\,kg^{-1}\,d^{-1}$ (maternal)	[182]
	20	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[182]

Chronic.

Rat (2-year feed):	2.5	$mg\,kg^{-1}\,d^{-1}$	[182]
Mouse (2-year feed):	187.5	$mg\,kg^{-1}\,d^{-1}$	[182]
Dog (6-month feed):	7.4	$mg\,kg^{-1}\,d^{-1}$	[182]

ADI: $0.03\,mg\,kg^{-1}\,d^{-1}$ [182]

Metalaxyl-M [*70630-17-0*]

LD_{50} (rat, oral)	667	mg/kg	[22, p. 274]
LD_{50} (rat, dermal)	>2000	mg/kg	[22, p. 274]
LC_{50} (rat, 4-h inhalation)	2.29	mg/L air	[22, p. 274]

Rabbit: nonirritating to skin [22, p. 274]
Rabbit: strong irritant to eyes [22, p. 274]
Guinea pig: not a skin sensitizer [22, p. 274]
Not mutagenic [22, p. 274]
NOEL/NOAEL:
Chronic.

Rat (2-year feed):	2.5	$mg\,kg^{-1}\,d^{-1}$	[22, p. 274]
Mouse (18-month feed):	35.7	$mg\,kg^{-1}\,d^{-1}$	[22, p. 274]
Dog (one-year feed):	8.0	$mg\,kg^{-1}\,d^{-1}$	[22, p. 274]

ADI: $0.025\,mg\,kg^{-1}\,d^{-1}$ [22, p. 274]

10.3.5. Phosphites

Fosetyl [*39148-24-8*]

LD_{50} (rat, oral)	5800	mg/kg	[154, p. 530]
LD_{50} (mouse, oral)	3700	mg/kg	[154, p. 530]
LD_{50} (rat, dermal)	>3200	mg/kg	[154, p. 530]
LD_{50} (rabbit, dermal)	>2000	mg/kg	[154, p. 530]
LC_{50} (rat, 4-h inhalation)	>0.0017	mg/L air	[154, p. 530]

Rabbit: nonirritating to skin [154, p. 530]
NOEL/NOAEL:
Subchronic.

Rat (90-day feed):	250	$mg\,kg^{-1}\,d^{-1}$	[154, p. 530]
Dog (90-day feed):	1250	$mg\,kg^{-1}\,d^{-1}$	[154, p. 530]

ADI: $3.0\,mg\,kg^{-1}\,d^{-1}$ [154, p. 530]

10.3.6. Inhibitors of Sterol Biosynthesis

The azole nitrogen of sterol biosynthesis inhibitors reacts with heme iron. These inhibitors have a high affinity for cytochrome P450. The synthesis of ergosterol is often inhibited at the C-14 demethylation step [183], which results in the accumulation of metabolite precursors. Some of these compounds have been reported to produce irritation of the gastrointestinal tract [184–193].

10.3.6.1. Triazoles

Azaconazole [*60207-31-0*]

LD_{50} (rat, oral)	308	mg/kg	[194]
LD_{50} (rabbit, oral)	324	mg/kg	[194]
LD_{50} (mouse, oral)	1123	mg/kg	[194]
LD_{50} (rat, dermal)	> 2560	mg/kg	[194]
LC_{50} (rat, 4-h inhalation)	1.22 – 1.84	mg/L air	[195]

Rabbit: nonirritating to eyes [194]
Rabbit: slightly irritating to skin [194]
Guinea pig: not a skin sensitizer [194]
Nonmutagenic [194]
NOEL/NOAEL:
Reproduction.

Rat (3-generation feed):	80	$mg\,kg^{-1}\,d^{-1}$ (parental and developmental)	[195]

Teratogenicity.

Rat (gavage):	10	$mg\,kg^{-1}\,d^{-1}$ (maternal)	[195]
	60	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[195]
Rabbit (gavage):	80	$mg\,kg^{-1}\,d^{-1}$ (maternal)	[195]
	160	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[195]

Chronic.

Rat (2-year feed):	12.5	$mg\,kg^{-1}\,d^{-1}$	[195]
Dog (6-month feed):	10	$mg\,kg^{-1}\,d^{-1}$	[195]

ADI: 0.1 $mg\,kg^{-1}\,d^{-1}$ [195]

Bitertanol [*55179-31-2*]

LD_{50} (rat, oral)	3300	mg/kg	[162, p. 47]
LD_{50} (mouse, oral)	4202	mg/kg	[162, p. 47]
LD_{50} (dog, oral)	> 5000	mg/kg	[162, p. 47]
LD_{50} (sheep, oral)	> 1000	mg/kg	[162, p. 46]
LD_{50} (rat, dermal)	> 5000	mg/kg	[162, p. 47]
LD_{50} (mouse, dermal)	> 5000	mg/kg	[162, p. 47]
LD_{50} (rabbit, dermal)	> 2000	mg/kg	[162, p. 47]

Guinea pig: not a skin sensitizer [209]
Nonmutagenic [162, p. 47]
NOEL/NOAEL:
Reproduction.

Rat (3-generation feed):	∼ 12	$mg\,kg^{-1}\,d^{-1}$ (parental and developmental)	[162, p. 47]

Teratogenicity.

Rat (gavage):	10	$mg\,kg^{-1}\,d^{-1}$ (maternal and developmental)	[162, p. 47]
Rabbit (gavage):	30	$mg\,kg^{-1}\,d^{-1}$ (maternal and developmental)	[162, p. 47]

Chronic.

Rat (2-year feed):	1	$mg\,kg^{-1}\,d^{-1}$	[169, p. 19]
Mouse (2-year feed):	3	$mg\,kg^{-1}\,d^{-1}$	[162, p. 47]
Dog (2-year capsule):	0.25	$mg\,kg^{-1}\,d^{-1}$	[169, p. 19]

ADI: 0.003 $mg\,kg^{-1}\,d^{-1}$ [169, p. 19]

Bromuconazole [*116255-48-2*]

LD_{50} (rat, oral)	365	mg/kg	[154, p. 124]
LD_{50} (mouse, oral)	151	mg/kg	[154, p. 124]
LD_{50} (rat, dermal)	> 2000	mg/kg	[154, p. 124]
LC_{50} (rabbit, 4-h inhalation)	> 5	mg/L air	[154, p. 124]

Rabbit: nonirritating to skin and eyes [154, p. 124]
Guinea pig: not a skin sensitizer [154, p. 124]
Nonmutagenic [154, p. 124]

Cyproconazole [*94361-06-5*]

LD_{50} (rat, oral)	1020 – 1330	mg/kg	[196]

Rat (2-generation feed):	0.62	$mg\,kg^{-1}\,d^{-1}$ (parental and developmental)	[172, p. 77]

Teratogenicity.

Rat (gavage):	10	$mg\,kg^{-1}\,d^{-1}$ (maternal)	[172, p. 77]
	40	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[172, p. 77]
Rabbit (gavage):	1.5	$mg\,kg^{-1}\,d^{-1}$ (maternal and developmental)	[172, p. 77]

Chronic.

Rat (2-year feed):	0.3	$mg\,kg^{-1}\,d^{-1}$	[172, p. 77]
Mouse (95-week feed):	3	$mg\,kg^{-1}\,d^{-1}$	[172, p. 77]
Dog (one-year feed):	3.2	$mg\,kg^{-1}\,d^{-1}$	[172, p. 77]

ADI: $0.003\,mg\,kg^{-1}\,d^{-1}$ [172, p. 77]

Tridemorph [*24602-86-6*]

LD_{50} (rat, oral)	400	mg/kg	[154, p. 1019]
LD_{50} (rat, dermal)	> 4000	mg/kg	[154, p. 1019]
LC_{50} (rat, 4-h inhalation)	4.5	mg/L air	[154, p. 1019]

Rabbit: severely irritating to skin and eyes [154, p. 1019]
NOEL/NOAEL:
Chronic.

Rat (2-year feed):	1.8	$mg\,kg^{-1}\,d^{-1}$	[154, p. 1019]
Mice (2-year feed):	> 13	$mg\,kg^{-1}\,d^{-1}$	[154, p. 1019]

Fenpropidin [*67306-00-7*]

LD_{50} (rat, oral)	> 1400	mg/kg	[154, p. 447]
LD_{50} (rat, dermal)	> 1800	mg/kg	[154, p. 447]
LC_{50} (rat, 4-h inhalation)	> 1.22	mg/L air	[154, p. 447]

Rabbit: irritating to skin and eyes [154, p. 447]
Guinea pig: not a skin sensitizer [154, p. 447]
Nonmutagenic [154, p. 447]
Nonteratogenic [154, p. 447]
ADI: $0.005\,mg\,kg^{-1}\,d^{-1}$ [154, p. 447]

10.3.6.7. Strobilurins

Azoxystrobulin [*131860-33-8*]

LD_{50} (rat, oral)	> 5000	mg/kg	[22, p. 70]
LD_{50} (rat, dermal)	> 2000	mg/kg	[22, p. 70]

Rabbit: slight skin and eye irritant [22, p. 70]
Guinea pig: not a skin sensitizer [22, p. 70]
Nonmutagenic [22, p. 70]
ADI: $0.2\,mg\,kg^{-1}\,d^{-1}$ [22, p. 70]

Kresoxim-methyl [*143390-89-0*]

LD_{50} (rat, oral)	> 5000	mg/kg	[22, p. 743]
LD_{50} (rat, dermal)	> 2000	mg/kg	[22, p. 743]
LC_{50} (rat, 4-h inhalation)	> 5.6	mg/L air	[22, p. 743]

Nonmutagenic [22, p. 743]
ADI: $0.4\,mg\,kg^{-1}\,d^{-1}$ [22, p. 743]

Metominostrobin [*133408-50-1*]

LD_{50} (rat, oral)	708 – 776	mg/kg	[22, p. 1147]
LD_{50} (rat, dermal)	> 2000	mg/kg	[22, p. 1147]
LC_{50} (rat, 4-h inhalation)	> 1.88	mg/L air	[22, p. 1147]

Rabbit: not a skin irritant [22, p. 1147]

10.3.7. Miscellaneous

Bupirimate [*41483-43-6*]

LD_{50} (rat, oral)	> 4000	mg/kg	[154, p. 127]
LD_{50} (mouse, oral)	> 4000	mg/kg	[154, p. 127]
LD_{50} (rabbit, oral)	> 4000	mg/kg	[154, p. 127]
LD_{50} (guinea pig, oral)	> 4000	mg/kg	[154, p. 127]
LD_{50} (rat, dermal)	4800	mg/kg	[154, p. 127]
LC_{50} (rat, 4-h inhalation)	>> 0.04	mg/L air	[154, p. 127]

Rabbit: mildly irritating to skin and eyes [154, p. 127]
Guinea pig: a moderate skin sensitizer [154, p. 127]
NOEL/NOAEL:
Subchronic.

Rat (90-day feed):	50	$mg\,kg^{-1}\,d^{-1}$	[154, p. 127]
Dog (90-day feed):	15	$mg\,kg^{-1}\,d^{-1}$	[154, p. 127]

Chronic.

Rat (2-year feed):	5	$mg\,kg^{-1}\,d^{-1}$	[154, p. 127]

Ethirimol [*23947-60-6*]

LD_{50} (rat, oral)	6340	mg/kg	[154, p. 409]
LD_{50} (mouse, oral)	4000	mg/kg	[154, p. 409]
LD_{50} (guinea pig, oral)	500 – 1000	mg/kg	[154, p. 409]
LD_{50} (rabbit, oral)	1000 – 2000	mg/kg	[154, p. 409]
LD_{50} (rat, dermal)	> 2000	mg/kg	[154, p. 409]
LC_{50} (rat, 4-h inhalation)	> 4.92	mg/L air	[154, p. 409]

Rabbit: nonirritating to skin [154, p. 409]
Rabbit: mildly irritating to eyes [154, p. 409]
NOEL/NOAEL:
Chronic.

Rat (2-year feed):	10	$mg\,kg^{-1}\,d^{-1}$	[154, p. 409]
Dog (2-year feed):	30	$mg\,kg^{-1}\,d^{-1}$	[154, p. 409]

Hymexazol [*10004-44-1*]

LD_{50} (rat, oral)	3909 – 4678	mg/kg	[154, p. 576]
LD_{50} (mouse, oral)	1968 – 2148	mg/kg	[154, p. 576]
LD_{50} (rat, dermal)	> 10 000	mg/kg	[154, p. 576]
LD_{50} (rabbit, dermal)	> 2000	mg/kg	[154, p. 576]

Rabbit: nonirritating to skin [154, p. 576]
Rabbit: irritating to eyes [154, p. 576]
Nonmutagenic [154, p. 576]
NOEL/NOAEL:
Chronic.

Rat (2-year feed):	19 – 20	$mg\,kg^{-1}\,d^{-1}$	[154, p. 576]
Dog (2-year feed):	15	$mg\,kg^{-1}\,d^{-1}$	[154, p. 576]

Isoprothiolane [*50512-35-1*]

LD_{50} (rat, oral)	1190	mg/kg	[154, p. 610]
LD_{50} (mouse, oral)	1340	mg/kg	[154, p. 610]
LD_{50} (rat, dermal)	> 10 250	mg/kg	[154, p. 610]

Rabbit: nonirritating to skin and eyes [154, p. 610]

Propamocarb [*24579-73-5*]

LD_{50} (rat, oral)	2000 – 8550	mg/kg	[154, p. 843]
LD_{50} (mouse, oral)	1960 – 2800	mg/kg	[154, p. 843]
LD_{50} (dog, oral)	1450	mg/kg	[154, p. 843]
LD_{50} (rabbit, dermal)	> 3920	mg/kg	[154, p. 843]
LC_{50} (rat, 4-h inhalation)	0.0057	mg/L air	[154, p. 843]

NOEL/NOAEL:
Chronic.

Rat (2-year feed):	10	$mg\,kg^{-1}\,d^{-1}$	[155, p. 179]
Dog (2-year feed):	25	$mg\,kg^{-1}\,d^{-1}$	[155, p. 179]

ADI: 0.1 $mg\,kg^{-1}\,d^{-1}$ [155, p. 179]

Pyroquilon [*57369-32-1*]

LD_{50} (rat, oral)	321	mg/kg	[154, p. 889]
LD_{50} (mouse, oral)	581	mg/kg	[154, p. 889]
LD_{50} (rat, dermal)	> 3100	mg/kg	[154, p. 889]
LC_{50} (rat, 4-h inhalation)	5.1	mg/L air	[154, p. 889]

Rabbit: mildly irritating to skin [154, p. 889]
Rabbit: slightly irritating to eyes [154, p. 889]
NOEL/NOAEL:
Chronic.

Rat (2-year feed):	30	$mg\,kg^{-1}\,d^{-1}$	[154, p. 889]

ADI: 0.015 $mg\,kg^{-1}\,d^{-1}$ [155, p. 889]

Tricyclazole [*41814-78-2*]

LD_{50} (rat, oral)	314	mg/kg	[154, p. 1017]
LD_{50} (mouse, oral)	245	mg/kg	[154, p. 1017]
LD_{50} (dog, oral)	> 50	mg/kg	[154, p. 1017]

LD_{50} (rabbit, dermal)	> 2000	mg/kg	[154, p. 1017]
LC_{50} (rat, one-h inhalation)	1.46	mg/L air	[154, p. 1017]

Rabbit: nonirritating to skin [154, p. 1017]
Rabbit: slightly irritating to eyes [154, p. 1017]
NOEL/NOAEL:
Chronic.

Rat (2-year feed):	13.8	$mg\,kg^{-1}\,d^{-1}$	[154, p. 1017]
Mouse (2-year feed):	57	$mg\,kg^{-1}\,d^{-1}$	[154, p. 1017]

Carpropamid [*104030-54-8*]

LD_{50} (rat, oral)	> 5000	mg/kg	[22, p. 744]
LD_{50} (mouse, oral)	> 5000	mg/kg	[22, p. 744]
LD_{50} (rat, dermal)	> 2000	mg/kg	[22, p. 744]
LC_{50} (rat, 4-h inhalation)	> 5.0	mg/L air	[22, p. 744]

Rabbit: nonirritating to skin and eyes [22, p. 744]
Guinea pig: not a skin sensitizer [22, p. 744]
Nonmutagenic [22, p. 744]
NOEL/NOAEL:
Chronic.

Rat (2-year feed):	400	$mg\,kg^{-1}\,d^{-1}$	[22, p. 744]
Dog (one-year feed):	200	$mg\,kg^{-1}\,d^{-1}$	[22, p. 744]

ADI: 0.014 $mg\,kg^{-1}\,d^{-1}$ [22, p. 744]

Spiroxamine [*118134-30-8*]

LD_{50} (rat, oral)	500 – 600	mg/kg	[22, p. 746]
LD_{50} (rat, dermal)	> 1600	mg/kg	[22, p. 746]
LC_{50} (rat, 4-h inhalation)	1.98 – 2.78	mg/L air	[22, p. 746]

Rabbit: severe skin irritant [22, p. 746]
Rabbit: not an eye irritant [22, p. 746]
Nonmutagenic [22, p. 746]
NOEL/NOAEL:
Chronic.

Rat (2-year feed):	3.50	$mg\,kg^{-1}\,d^{-1}$	[22, p. 746]
Mice (18-month feed):	2.85	$mg\,kg^{-1}\,d^{-1}$	[22, p. 746]
Dog (one-year feed):	1.88	$mg\,kg^{-1}\,d^{-1}$	[22, p. 746]

ADI: 0.025 $mg\,kg^{-1}\,d^{-1}$ [22, p. 746]

Probenazole [*27605-76-1*]

LD_{50} (rat, oral)	2030	mg/kg	[22, p. 999]
LD_{50} (mouse, oral)	2750 – 3000	mg/kg	[22, p. 999]
LD_{50} (rat, dermal)	> 5000	mg/kg	[22, p. 999]

Nonmutagenic [22, p. 999]
NOEL/NOAEL:
Chronic.

Rat (2-year feed):	22.5	$mg\,kg^{-1}\,d^{-1}$	[22, p. 999]

Teratogenicity.

Rat (gavage):	150	$mg\,kg^{-1}\,d^{-1}$	[22, p. 999]

Fenpropidin [*67306-00-7*]

LD_{50} (rat, oral)	> 1447	mg/kg	[22, p. 526]
LD_{50} (rat, dermal)	> 4000	mg/kg	[22, p. 526]
LC_{50} (rat, 4-h inhalation)	> 1.22	mg/L air	[22, p. 526]

Rabbit: skin and eye irritant [22, p. 526]
Guinea pig: not a sensitizer [22, p. 526]
Nonmutagenic [22, p. 526]
NOEL/NOAEL:
Chronic.

Rat (2-year feed):	0.5	$mg\,kg^{-1}\,d^{-1}$	[22, p. 526]
Mouse (18-month feed):	4.5	$mg\,kg^{-1}\,d^{-1}$	[22, p. 526]
Dog (one-year feed):	2.0	$mg\,kg^{-1}\,d^{-1}$	[22, p. 526]

ADI: 0.005 $mg\,kg^{-1}\,d^{-1}$ [22, p. 526]

Famoxadone [*131807-57-3*]

LD_{50} (rat, oral)	> 5000	mg/kg	[22, p. 500]
LD_{50} (rat, dermal)	> 2000	mg/kg	[22, p. 500]

Rabbit: nonirritating to skin and eyes [22, p. 500]
Nonmutagenic [22, p. 500]

Quinoxyfen [*124495-18-7*]

LD_{50} (rat, oral)	> 5000	mg/kg	[22, p. 1083]
LD_{50} (rat, dermal)	> 2000	mg/kg	[22, p. 1083]
LC_{50} (rat, 4-h inhalation)	> 3.38	mg/L air	[22, p. 1083]

Rabbit: mildly irritating to eyes [22, p. 1083]
Rabbit: not a skin irritant [22, p. 1083]
Guinea pig: not a sensitizer [22, p. 1083]
Nonmutagenic [22, p. 1083]
ADI: 0.2 $mg\,kg^{-1}\,d^{-1}$ [22, p. 1083]

Detailed information is given on the production, properties, and economical aspects of furfural [*98-01-1*] and furfuryl alcohol [*98-00-0*], and the most important specialty chemicals derived from furfural and furfuryl alcohol are summarized: furan [*110-00-9*], tetrahydrofurfuryl alcohol [*97-99-4*], 3,4-dihydro-2*H*-pyran [*110-87-2*], furfurylamine [*617-89-0*], tetrahydrofurfurylamine [*4795-29-3*], 2-methylfuran [*534-22-5*], 2-methyltetrahydrofuran [*96-47-9*], and furoic acid [*88-14-2*].

1. Introduction

This article discusses the properties, production, and industrial uses of furfural and compounds derived from furfural on a commercial basis. The only commercial route to furfural is acid-catalyzed digestion of pentosan sugars in biomass. Nowadays, furfural is the sole precursor for all molecules containing a furyl, furfuryl, furoyl, or furfurylidene radical in the chemical industry.

History. In 1831 J. Döbereiner isolated a yellow oily substance when he treated carbohydrates with H_2SO_4 and MnO_2. In 1845 the same substance with molecular formula $C_5H_4O_2$ was prepared by G. Fownes by acid digestion of bran and named furfural (Latin *furfur* = bran). Almost 100 years after its discovery, commercial production of furfural from oat hulls was started by the Quaker Oats Company in 1922 at their cereal mill in Cedar Rapids, Iowa producing several

Scheme 1. Chemicals derived from furfural

tons per month. Discovery of the applicability of furfural in oil refining and phenol–furfural resins led to an important increase in furfural production capacities in the 1930s and 1940s. In 1934 furfuryl alcohol was made commercially available by the Quaker Oats Company by high-pressure reduction of furfural. Today this alcohol is still the largest volume derivative of furfural. In 1949 Du Pont disclosed a new route to adiponitrile for the manufacture of nylon 66 from furfural. This four-step process with furan, tetrahydrofuran, and dichlorobutane as intermediates led to an important additional increase in furfural production during the 1950s. In 1961 Du Pont abandoned this furfural-based production process because tetrahydrofuran, the key intermediate, could be made from petrochemical C_4 hydrocarbons or acetylene and formaldehyde

(Reppe process). In 1955 tetrahydrofurfuryl alcohol, a water-miscible solvent, was made commercially available from furfuryl alcohol. After the introduction of the furan no-bake process for the production of casting molds in 1958, the foundry industry became a major consumer of resins based on furfural and furfuryl alcohol. Improved versions of these resins became available in the furan hot-box (1962) and furan warm-box (1978) processes. In 1985 furfuryl alcohol became a key intermediate in the pharmaceutical industry for the production of ranitidine, an antiulcer drug. In today's chemical industry furfural is the precursor for (Scheme 1)

- Furfuryl alcohol and tetrahydrofurfuryl alcohol
- 3,4 Dihydro-2*H*-pyran
- 5-(Dimethylaminomethyl)furfuryl alcohol,
- α-Methylfurfuryl alcohol,
- Levulinic acid
- 2-Methylfuran and 2-methyltetrahydrofuran
- Furan
- 2,2-Difurylpropane and 2,2-bis(tetrahydrofurfuryl)propane
- 2,5-Dimethoxy-2,5-dihydrofuran
- α-Acetylfuran
- Pyrrole
- Furfurylamine and tetrahydrofurfurylamine
- Piperidine
- Furoic acid, furoic esters, and tetrahydrofuroic acid

2. Furfural

2.1. Properties

2.1.1. Physical Properties

Furfural [*98-01-1*], 2-furancarbonal, 2-furaldehyde, furfuraldehyde, $C_5H_4O_2$, M_r 96.08, has an aromatic odor reminiscent of almonds. Its exceptional physical properties make this heteroaromatic aldehyde a selective extractant for removing aromatics from lubricating oils and diesel fuels. Detailed information on the solvent applications of furfural can be found in [1]. Furfural forms an azeotrope with water at atmospheric pressure (65 wt % water, *bp* 97.85 °C). General physical properties of furfural are given in Table 1. Equations for calculation of some physical properties are presented in Table 2.

Table 1. Physical properties of furfural

M_r	96.08
bp at 101.3 kPa, °C	161.7
fp, °C	−36.5

	(ΔH_{vap} in J/mol and T in K)	$b = 0.3126$

2.1.2. Chemical Properties

Furfural undergoes reactions typical for aldehydes like acetalization, acylation, aldol and Knoevenagel condensations, reduction to alcohols, reductive amination to amines, decarbonylation, oxidation to carboxylic acids, and Grignard reactions. The furan ring can be subjected to alkylation, hydrogenation, oxidation, halogenation, and nitration reactions. Due to the electron-withdrawing effect of the carbonyl group, the furan ring of furfural is less susceptible to hydrolytic ring cleavage and Diels–Alder cycloaddition reactions.

Alkylation (Arylation). Furfural undergoes common Friedel–Crafts alkylations, for example, with chlorinated hydrocarbons [2–4]. The 5-position is most susceptible to alkylation reactions. Use of large amounts of acid catalyst and high reaction temperature should be avoided to prevent extensive resinification of furfural. Another method to alkylate furfural in its 5-position is oxidative coupling catalyzed by Pd acetate in the presence of an olefin as alkenylating agent. In the case of acrylic esters this reaction proceeds with moderate yields and Pd-based turnover numbers [5, 6]. Furfural and 5-bromofurfural can be coupled by photochemical aryl coupling to form 5,5′-diformyl-2,2′-difuran [7]. If this reaction is carried out in the presence of an acid scavenger the dialdehyde can be produced in high yields. Photochemical production of 5,5′-diformyl-2,2′-difuran has been patented [8].

5,5-Diformyl-2,2'-difuran

Cannizzaro Reactions. The Cannizzaro reaction of furfural in alcoholic KOH solution yields equimolar amounts of potassium furoate and furfuryl alcohol [9]. Cannizzaro reactions of furfural can also be performed under solvent-free conditions [10] and under microwave irradiation [11]. The Cannizzaro reaction of furfural is currently used for the production of furoic acid (see Chapter 8).

Acetalization and Acylation. Like any other aldehyde furfural undergoes acetalization with various alcohols [12, 13].

Furfuryl acetal

If the reaction water is removed, the reaction can be brought to completion with or without an acid catalyst [14–16]. More recently Ce^{3+}-exchanged montmorillonite clays and mesoporous aluminosilicates were found to be efficient and reusable inorganic heterogeneous catalysts for the production of acetals of furfural [17, 18].

Furfural can be acylated with acid anhydrides. In the presence of acetic anhydride and stannous chloride as catalyst, furfuryl diacetate is formed [19]. More recently other acid catalysts have been applied, such as H-Nafion [20], $FeCl_3/SiO_2$ under microwave irradiation [21], Fe^{3+}-exchanged montmorillonite [22], HY zeolite [23], and heteropolyacids such as $H_6P_2W_{18}O_{62}\cdot H_2O$ [24].

Furfuryl diacetate

Condensation Reactions. In the presence of alkaline catalysts, generally NaOH or KOH, furfural undergoes a crossed aldol reaction with aldehydes having α-hydrogen atoms [25–31]. A typical reaction is the condensation of furfural with α-phenylacetaldehyde to give 2-phenyl-3-(2-furyl)propenal.

2-Phenyl-3-(2-furyl)-propenal

When the compound with an active α-hydrogen atom is an ester, acid, or a nitrile, this base-catalyzed reaction is called a Knoevenagel

condensation [32–34]. Microwave-assisted and solvent-free procedures in the presence of heterogeneous catalysts have received some attention [35, 36].

Reduction and Reductive Amination. Furfural reduction, the principal reaction in today's furfural industry, is used for the production of furfuryl alcohol (Section 3.2), tetrahydrofurfuryl alcohol (Section 5.1), furfurylamine, and tetrahydrofurfurylamine (Chap. 6).

Decarbonylation. Decarbonylation of furfural to furan and CO or CO_2 and H_2 is discussed in Section 4.2.

Oxidation. The aldehyde group of furfural easily undergoes catalytic oxidation to furoic acid in the presence of oxygen, air, or hydrogen peroxide. Details of these liquid-phase reactions are given in Chapter 8.

At high temperatures (320 °C) furfural can be oxidized with air to maleic anhydride with a maximum yield of 25 % over MoO_3–V_2O_5 catalysts [37, 38].

Photooxidation of furfural with singlet dioxygen yields 5-hydroxy-2(5*H*)-furanone (80 %), a highly versatile compound in organic synthesis and a key constituent of a number of biologically active compounds [39]. In this reaction, singlet oxygen is generated from O_2 with sensitizers like rose Bengal or methylene blue under sunlight irradiation. 5-Hydroxy-2(5*H*)-furanone can be used directly as fungicide or insecticide. This reaction was patented by BASF in 1971 [40].

5-Hydroxy-2(5*H*)-furanone

Halogenation and Nitration. Furfural can be halogenated and nitrated at the 5-position to form 5-halo-2-furfuraldehyde and 5-nitro-2-furfuraldehyde [41]. Chlorination occurs in CS_2 by direct reaction of furfural with chlorine, whereas 5-bromo-2-furfuraldehyde can only be formed by the action of bromine on furfuryl diacetate. Nitration of furfural can be performed with fuming nitric acid in acetic anhydride at −10 °C. Hydrolysis of the nitrated furfural diacetate results in 5-nitro-2-furfuraldehyde.

5-Nitro-2-furfuraldehyde

5-nitro-2-furfuraldehyde and 5-nitro-2-furfuraldehyde diacetate are the key components in the manufacture of various synthetic antimicrobial nitrofuran pharmaceuticals.

Grignard Reaction. The reaction between furfural and an organomagnesium halide (Grignard reagent) yields secondary furfuryl alcohols. This reaction is currently used in manufacturing α-methylfurfuryl alcohol, the precursor for maltol.

α-(Methyl)furfuryl alcohol

Alternatively, α-methylfurfuryl alcohol can be obtained by reduction of α-acetylfuran, but this route is not employed in today's furfural-based industry.

Resinification. Furfural is very sensitive to resinification [42]. On heating, furfural undergoes self-condensation reactions in both acid and alkaline media. In the initial stage of polymerization furfural undergoes two different reactions, namely, the formation of difuryl ketonic aldehyde (**10**) and trifurylic dialdehyde (**11**). The latter is responsible for further polymerization, which yields a black cross-linked polymer. Because of the high reactivity of the tertiary H atom in **2**, conjugated systems with strongly delocalized electron pairs are formed, which lead to the black color of the resin.

Figure 2. Integration of furfural production in the manufacture of sucrose from sugar cane

2.2. Resources and Raw Materials

The only route to furfural in today's chemical industry is the acid-catalyzed digestion of hemicellulose-rich agricultural wastes. Hemicelluloses are next to cellulose the most abundant biobased polymers in the biosphere and mainly consist of C_5 polysaccharides, or pentosans. Biomass with a substantial amount of pentosan sugar can be used as raw material for furfural production (Fig. 1). The C_5 polysaccharides are hydrolyzed by an acid catalyst to monosaccharides, which are dehydrated to furfural.

Figure 1. Pentosan content (dry substance) of raw materials for furfural production

On industrial scale the pentosan content, price, local availability, and costs for collection, transportation, and handling of the raw material greatly determine the profitability. Corncobs and bagasse from sugar cane are the major industrial feedstocks for furfural production. The high bulk density and pentosan content make furfural production from corncobs feasible. Nevertheless, high collection and transportation costs can be a drawback. Although bagasse is difficult to handle (low bulk density), the largest furfural production plants are located at sugar mills where sugar cane is being processed. In this process sucrose is extracted from the sugar cane. The resulting waste, bagasse, is digested to furfural (Fig. 2).

The common raw materials used for furfural production differ by region (Table 3). Next to the use of these renewable resources, furfural is produced as a byproduct from sulfite pulping of wood. During the pulping process a minor quantity of pentosan sugars is dehydrated to furfural, which can be recovered by distillation. The rest of the pentosan fraction can be extracted and purified to obtain xylose for xylitol production [43].

Table 3. Use of raw materials for furfural production by region (2004)

Raw material	Region
Bagasse	Dominican Republic, Thailand, India; South Africa
Corncobs	China
Almond shells, apricot and olive seeds	Spain
Quebracho, chestnut, birch and aspen wood	Argentina; Slovenia; Russia
Sulfite black liquor of wood pulping	Austria

2.3. Production

2.3.1. Chemistry of Furfural Production

Furfural is produced from the pentosan sugar fraction of biomass. This pentosan fraction consists of polysaccharides of C_5 sugars and is generally built up from a backbone of 1,4-linked β-D-xylopyranosyl residues or xylan. The xylan backbone contains α-L-arabinofuranose groups attached at various positions. Therefore, these structures are called arabinoxylans (**1**). In the production of furfural, arabinoxylans are first hydrolyzed by acids to the monosaccharides L-arabinofuranose (**2**) or L-arabinose (**3**) and D-xylopyranose (**4**) or D-xylose (**5**) (see below).

Some hydroxyl groups of arabinoxylan (**1**) are acylated with short fatty acids like acetic acid. These esters are also hydrolyzed to the corresponding carboxylic acids **6**.

In the second step monosaccharides are dehydrated to furfural. The dehydration pathway is presented for D-xylose; a similar pathway can be considered for conversion of arabinose to furfural. A generally accepted pathway for the dehydration occurs through the 1,2-enediol form (**7**) of xylose. A first water molecule is abstracted at the 3-position to produce 3-deoxy-D-xylosulose (**8**) in its enolic form. Further dehydration at the 4-position yields 3,4-dideoxy-D-xylo-3-pentenosulose (**9**), which is converted to the cyclic acetal and finally to furfural by loss of a third water molecule. The hydrolysis of the pentosan fraction to monomeric C_5 sugars is approximately 50 times faster than the dehydration to furfural. The kinetics of these reactions have been studied in detail [44–48].

Some pentosan monosaccharides contain additional methyl groups at the 1- or 5-position. On dehydration these sugars yield respectively 2-furyl methyl ketone (2-acetylfuran) and 5-methylfurfural. These two products are common impurities (<1 wt %) in commercial furfural. Acetaldehyde, another byproduct, results from the acid digestion of coniferylaldehyde, which is present in some raw materials. Under industrial reaction conditions acetaldehyde can be converted to 2,3-butanedione and 2,3-

pentanedione by a radical reaction with oxygen. If they are formed in furfural production, these highly valuable diketones are generally recovered from crude furfural by distillation.

Under industrial conditions not all of the pentosan sugars are converted to furfural. As a substantial amount of product and substrate are lost in side reactions, yields never exceed 55 % of the theoretical maximum. Acetalization of pentose with furfural is the most important yield-lowering side reaction.

The choice of acid catalyst used under industrial conditions is restricted to the mineral acids H_2SO_4 and H_3PO_4. HNO_3 cannot be used due to corrosion problems and loss of product by formation of nitrated and oxidized products. Some processes are operated without addition of acid catalyst and rely on the acidity of the thermally produced carboxylic acids.

The analytical method for the determination of the total pentosan content of the raw materials can also rely on the acid dehydration of pentoses to furfural [49, 50]. In this system the formed furfural is instantaneously vaporized due to its insolubility in the boiling reaction medium. In common industrial reactors, the reaction medium cannot be brought to its boiling temperature because heating is always effected by the introduction of superheated steam, the condensation temperature of which is below the boiling point of the reaction medium.

2.3.2. Production of Furfural

Furfural production processes can be roughly divided into low- and high-temperature processes. Most commercial units are operated under low-temperature (< 190 °C) conditions. Reactors are always heated by introduction of superheated steam. The furfural yield of these processes, based on the pentosan content, is typically around 50 %.

Industrial Processes. The oldest furfural process was started in 1921 by the Quaker Oats Company [51]. In the *Quaker Oats batch process*, reactors are lined with carbon bricks sealed by acid-proof cement. Air-dried biomass, for example, dried oat hulls, is mixed with aqueous sulfuric acid at a H_2SO_4 to dry biomass weight ratio of 0.02. Steam injection is used to heat the rotary reactor to 153 °C and to remove the formed furfural. After 5 h the reaction is completed and the acid residue is separated into spent liquor and digested biomass. Quaker Oats issued some variants of this basic design regarding reactor setup [52–54], furfural removal [55], and material pretreatment [56]. Optimized versions of the Quaker Oats batch process are still in use in furfural manufacturing.

The simplest variant of the Quaker Oats batch process is the current *Chinese batch method*. In this process, the reactors have no lining; instead, mild-steel reactors with 50 mm wall thickness are employed. Additionally, fouling by furfural-derived polymers protects the inner wall of the reactor against corrosion.

The *Agrifurane process*, now abandoned, was operated with slurry mixtures rather than with loose material to permit the use of fines. Several batch reactors (161–177 °C) are operated in series in order to reduce steam consumption [57–59].

After using the batch process for almost 50 years the Quaker Oats Company developed the *Quaker Oats continuous process*, with a full-scale continuous plant at Belle Glade, Florida (1966–1997). The central part of this process was a brick-lined horizontal reactor which was fed with moisturized raw material. Admission of superheated steam and dilute sulfuric acid brought the contents to 184 °C. The Quaker Oats continuous process produced furfural with the same yield as the batch process, but without continuous steam stripping and with a fivefold decrease in residence time. This innovative plant was operative for more than 30 years before it was shut down in 1997 because the cost of raw materials, labor, and maintenance rendered furfural production in the USA unprofitable.

Other continuous processes are the Escher Wyss process and the Rosenlew process. In the now abandoned *Esher Wyss process* [60] furfural was produced in a fluidized bed of biomass in a vertical column reactor. With continuous charge

and discharge of raw material, this resulted in a wide distribution of residence times, as is also observed in common continuous stirred tank reactors. This caused a dramatic yield loss compared to simple batch reactions. *The Rosenlew process* [61] is comparable to the Escher Wyss process. The reactor is also a column-type reactor with charge at the top and discharge at the bottom and a countercurrent flow of steam, but the raw material is not mixed by fluidization. Instead, as in a moving-bed reactor, slow transport of material from top to bottom results in a narrow residence-time distribution and acceptable furfural yields. Both Esher Wyss and Rosenlew processes can be operated without the addition of extra acid; the reactions are catalyzed by autocatalytically formed carboxylic acids.

Novel and Future Processes. Challenges for future processes are to increase furfural yield and to optimize the energy efficiency of furfural plants.

Early work [47] showed that furfural yield from aqueous mixtures of xylose increases with increasing reaction temperature. However, continuous steam stripping of the reaction does not significantly improve yields. Implementation of this knowledge can be found already in the Quaker Oats continuous process, which operated at 184 °C without steam stripping of the formed furfural. More recently patented processes utilize even higher reaction temperatures, preferentially above 220 °C. At these high temperatures residence times are decreased to a few minutes; this allows the use of small reactors.

The *Suprayield process* [62–64] operates at high temperature and pressure. However, the design allows the reaction mixture to boil by gradual decompression of the reactor at high temperature. Furfural is insoluble in the boiling reaction mixture and is spontaneously transferred to the vapor phase. In this manner furfural is removed more effectively than by stripping steam. Since the formed furfural is quickly removed from the liquid phase, it cannot participate in yield-lowering side reactions. In comparison with traditional methods superior yields (70 %) were obtained in a pilot-scale setup.

Biorefinery Processes In all the processes mentioned above, refining of the biomass is restricted to furfural formation. After reaction, the digested raw material is burned to meet the energy demand of the furfural production plant or used as fertilizer after neutralization. Hence, only the C_5 carbohydrate fraction of the biomass is utilized. Next to the acid digestion of pentosans to furfural, the hexose polysaccharides (e.g., cellulose) can be used for the production of levulinic acid. The hexosan fraction needs a hydrolysis temperature of 200 °C in the presence of dilute aqueous H_2SO_4 in order to release hexose monosaccharides. Under these conditions hexoses are dehydrated to 5-(hydroxymethyl)furfural which is hydrolyzed to levulinic and formic acids [65–70]. A plant for the production of levulinic acid from cellulose-rich materials is currently (2006) being set up by Le Calorie s.p.a in Caserta, Italy. Levulinic acid is a potential precursor for 2-methyltetrahydrofuran (Chap. 7).

Another example of utilization of the C_6 carbohydrate fraction is the production of ethanol and furfural from deciduous wood and agricultural waste. In 1926 G. Scholler reported the percolation hydrolysis of coniferous wood to obtain glucose and subsequently ethanol by fermentation. In this process, dilute sulfuric acid was continuously filtered through a layer of wood chips at elevated pressure and temperature to depolymerize cellulose to glucose. Whereas coniferous wood has a total pentosan content of 5 wt %, deciduous wood like beech- and birchwood contains up to 25–28wt % pentosan sugars. Therefore, the production of ethanol and furfural from deciduous wood and agricultural waste is very interesting. Nevertheless, in traditional furfural production processes and the percolation-hydrolysis method, 40–50 % of the cellulose is destroyed during furfural formation when biomass with high pentosan content is

used. Hence, these processes cannot be adapted for the combined economic production of ethanol and furfural. According to the process developed by N. Vedernikov, furfural can be produced in 70 % yield from biomass with preservation of the cellulose part [71–73]. The new technology, which allows the fermentative production of ethanol from the lignocellulosic residue after the production of furfural by using the cooperative catalytic effect of concentrated sulfuric acid and thermally produced carboxylic acids, was implemented in 1997 in Russia. In the case of birch and aspen wood as raw materials, the plant capacity is 11 (10^6 L/a of ethanol and 4000 t/a of furfural.

Distillation of Water–Furfural Product Vapor. In all known furfural manufacturing processes, the output of the acid digestion reactor is furfural in water vapor containing various byproducts. The process diagram of a furfural distillation plant is presented in Figure 3. Product vapors are condensed before they are injected into the azeotropic distillation column (A) at atmospheric pressure. In this column the water–furfural azeotrope is purified from low boilers such as methanol and high boilers comprising carboxylic acids such as acetic acid. The purified water–furfural vapor is then condensed and fed to a decanter (C) where an aqueous and an organic phase are formed. The light aqueous phase, which contains a small amount of furfural, is recycled to the azeotrope distillation column. The heavy layer (94 % furfural) is neutralized with alkali (D) and undergoes an additional vacuum distillation (E) to yield pure anhydrous furfural. The head fraction of this vacuum column contains the water–furfural azeotrope, which is recycled to the static decanter. The bottom fraction consists of a small amount of furfural polymers.

2.4. Uses and Economic Aspects

Uses. Of the world production of furfural 60–70 % is converted to furfuryl alcohol. The remaining part (50 000 t in 2003) is used as:

- Extractant for aromatics from lubricating oils
- Purification solvent for C_4 and C_5 hydrocarbons
- Reactive solvent and wetting agent
- Chemical feedstock for other furan derivatives
- Nematode control agent

Furfural is used as selective solvent in the refining of lubricating oils. The first refining unit was built by a subsidiary of Texaco, the Indian Refining Company, in 1933. This technology led to production of high-quality motor oil with improved temperature–viscosity properties. Aromatics, polar components, mercaptans, and others are removed from petroleum by means of furfural extraction. Furfural can also be used as decolorizing agent to refine crude wood rosin. During World War II purification technology for butadiene was developed in the United States for the manufacture of synthetic rubber. By extractive distillation with furfural, butadiene and isoprene can be separated from saturated C_4 and C_5 hydrocarbons, respectively. Detailed information about solvent uses of furfural can be found in [1].

Figure 3. Furfural distillation plant
A) Azeotropic distillation column; B) Heat exchangers (CW = cooling water); C) Static decanter; D) Stirred neutralizer; E) Vacuum distillation column; F) Vacuum pump

Furfural is unusually effective as a solvent for phenolic resins. In the manufacture of abrasive wheels, brake linings, and refractory products for the steel industry furfural is known as a reactive solvent and excellent wetting agent.

Next to the production of furfuryl alcohol, furfural is a chemical feedstock for the production of other 5-membered oxygen-containing heterocycles such as furan, methylfuran, acetylfuran, furfurylamine, and furoic acid.

In South Africa furfural has recently been introduced by Illovo Sugar Ltd as an active ingredient in Crop Guard to control plant-parasitic nematodes in the soil. Existing nematicides are effective but generally more toxic (e.g., methyl bromide). Extensive research has shown that Crop Guard is selective in suppressing parasitic nematodes. Crop Guard reacts with the cuticle of the nematode. In this way nematodes are immobilized and destroyed. Crop Guard finds application for the cultivation of tomatoes, groundnuts, peppers, and maize [74].

Economic Aspects. In 2003, world production of furfural excluding the former USSR was 200 000 t. The last two decades have witnessed an enormous expansion of furfural producing facilities in the China. Today, small furfural producers in eight different provinces represent half of world capacity. In the USA, too-high manufacturing costs rendered furfural production economically impossible. The last furfural plant, at Cedar Rapids, was closed in 2004. Nowadays, furfural activities are totally concentrated in developing countries with cheap labor, favorable climate, and fertile land. The largest single-site producer is located in the Dominican Republic. The evolution of furfural production in Asia, South and North America, and Europe excluding the former USSR is presented in Table 4.

2.5. Quality Specifications, Transportation, Toxicology

Quality Specifications. On the international market furfural must meet the specifications listed in Table 5.

Table 5. Furfural specifications on the international market

Furfural (GC assay) wt %	99 (min.)
Moisture, wt %	0.2 (max.)
Acidity, meq/L	20 (max.)
Residue, wt%	0.5 (max.)

Transportation. Furfural is shipped in tankers, steel tank trucks, aluminum tank trucks, ISO containers, IBCs, and steel drums. Drum lots may be stored for months without appreciable change in physical properties. Bulk storage under nitrogen is always recommended to prevent darkening of furfural. Due to its relatively high boiling point (161.7°C), it is difficult to build up substantial concentrations of furfural in the atmosphere. If ignited, the fire can be controlled by the use of water, foam, carbon dioxide, or dry chemicals. Furfural should not be mixed with strong acids or alkalis nor stored near strong oxidizing chemicals

Toxicology. Furfural is virtually ubiquitous in nature; together with furfuryl alcohol, it occurs naturally in many fruits and in tea, coffee (55–255 mg/kg), cocoa and alcoholic beverages

(1–33 mg/kg), and whole grain bread (up to 26 mg/kg). Furfural is listed in the register of chemically defined flavoring substances (EC, 2002).

Table 6. Toxicological data for furfural

Furfural is harmful in contact with skin, toxic by inhalation or swallowing, irritating to eyes and respiratory system, but not sensitizing to skin. There is only limited evidence of any carcinogenic effect. In an in vivo gene mutation study on transgenic Muta-mice, furfural was not found to be a direct-acting carcinogen. Orally applied furfural was unable to induce gene mutations in vivo [75]. Furfural is not toxic to reproduction.

In rats and mice furfural is rapidly metabolized; the major part is oxidized to furoic acid, which is excreted either free or conjugated with glycine (in humans). The smaller part condenses with acetic acid [76]. Detailed toxicological data are summarized in Table 6. Furfural is readily biodegradable in both aerobic and anaerobic degradation tests.

3. Furfuryl Alcohol

3.1. Properties

3.1.1. Physical Properties

Furfuryl alcohol [*98-00-0*], furanol, 2-furanmethanol, 2-(hydroxymethyl)furan, $C_5H_6O_2$, M_r 98.10, is a mobile colorless or pale yellow liquid with mild odor. Furfuryl alcohol forms an azeotrope with water at atmospheric pressure (80 wt % water, *bp* 98.5 °C). General physical properties of furfuryl alcohol are given in Table 7. Equations for calculation of some physicochemical properties are presented in Table 8.

3.1.2. Chemical Properties

Furfuryl alcohol can be derivatized by alkylation, cycloaddition, (trans)esterification, ether-

Table 8. Equations for calculation of physical properties of furfuryl alcohol.

Physical property	Equation	Constants
Vapor pressure	$p_i = \exp(a + b/T + c\ln(T) + dT^2)$ (p_i in Pa and T in K)	$a = 77.274$ $b = -8715.5$ $c = -7.9113$ $d = 4.7922 \times 10^{-3}$
Surface tension	$\sigma = a.(1 - T)^b$ (σ in N/m and T in K)	$a = 0.07217$ $b = 1.006$
Heat capacity at constant pressure		
liquid	$C_p = a + bT$	$a = 101.2$ $b = 0.337$
vapor	$C_p = a + b[(c/T)/\sinh(c/T)]^2 + d[(e/T)/\cosh(e/T)]$ (C_p in J/mol.K and T in K)	$a = 169.17$ $b = 117.3$ $c = 1229$ $d = -78470$ $e = 7.742$
Enthalpy of evaporation	$\Delta H_{vap} = a.(1\text{-}T)^b$ (ΔH_{vap} in J/mol and T in K)	$a = 68820$ $b = 0.2876$
Viscosity liquid	$\mu = \exp(a + bT + cT^2)$	$a = -37.008$ $b = 3555$ $c = 3.4664$
vapor	$\mu = (a \cdot T^b)/(1 + c/T)$ (μ in Pa·s and T in K)	$a = 2.9819 \times 10^{-7}$ $b = 0.6658$ $c = 233.43$

ification, hydrogenation and hydrogenolysis, oxidation, and halogenation reactions.

Alkylation. Furfuryl alcohol is generally alkylated at the 5-position when it undergoes electrophilic aromatic substitution. Under acid conditions, furfuryl alcohol is hydroxymethylated to 2,5-bis(hydroxymethyl)furan with formaldehyde.

2,5-Bis(hydroxymethyl)furan

At low molar formaldehyde/furfuryl alcohol ratios (2–5) this reaction can be catalyzed by homogeneous carboxylic acids [77, 78] and by acidic ion-exchange resins [79], though the selectivity towards 2,5-bis(hydroxymethyl)furan is low. At high molar ratios (> 110) the reaction can be catalyzed with high yield using dealuminated H-mordenite zeolites [80, 81]. This zeolite-based process was patented in 1995 [82].

Furfuryl alcohol can also undergo Mannich-type reactions. In the presence of formaldehyde and dimethylamine, 5-(dimethylaminomethyl)furfuryl alcohol can be prepared with 70 % yield. 5-(Dimethylaminomethyl)furfuryl alcohol is the precursor for the production of ranitidine, an anti-ulcer drug. This reaction can be performed with or without acetic acid as catalyst at moderate temperature (70–100 °C) [83, 84].

5-(Dimethylaminomethyl)furfuryl alcohol

Cycloadditions. Furfuryl alcohol readily undergoes Diels–Alder cycloaddition with dienophiles like maleic anhydride. In the case of maleic anhydride the reaction solvent determines whether the normal Diels–Alder (NDA) product or the derived lactone is formed [85–87].

NDA

Lactone

Self-Resinification. The primary alcohol function of furfuryl alcohol can be protonated to form an electrophilic carbocation, which can attack another furfuryl alcohol molecule in an electrophilic aromatic substitution reaction to yield polyfurfuryl alcohol.

Polyfurfuryl alcohol is a black, highly cross-linked thermoset polymer which is of great interest in the foundry industry. To avoid a violent explosive reaction due to exothermicity, the polymerization should not be carried out with strong Brønsted or Lewis acids. Belgacem and Gandini elucidated the complicated structure of polyfurfuryl alcohol [88, 89]. Based on reactions with model compounds mimicking properties of monomer and oligomer fractions, they proposed the formation of highly conjugated structures by consecutive hydride and proton abstractions from the polyfurfuryl alcohol chain. These conjugated systems are responsible for chromophore formation and are believed to be the active species in cross-linking by Diels–Alder-type reactions (Fig. 4).

Esterification (Transesterification). In view of the acid sensitivity of furfuryl alcohol, base-catalyzed transesterification is preferred to prepare furfuryl esters. Nevertheless, recently developed Lewis and Brønsted acid catalysts have been found useful for the synthesis of furfuryl esters in esterification and transesterification reactions. β-Keto esters can be prepared by using montmorillonite K10 clay or yttria–zirconia as transesterification catalysts [90, 91]. Furfuryl alcohol can be acetylated with acetic anhydride in presence of $Bi(OTf)_3$ [92] and $LiClO_4$ [93], whereas acetic acid can be used as acyl donor in an esterification catalyzed by yttria–zirconia [94].

Figure 4. Mechanisms of chromophore formation and cross-linking during the self-resinification of furfuryl alcohol

Etherification. Furfuryl ethers can be formed by normal Williamson ether synthesis in strongly basic media. This method is frequently used in organic synthesis [95–99]. Tetrahydropyranyl ethers of furfuryl alcohol can be formed with 3,4-dihydro-2*H*-pyran in the presence of a catalyst such as HY zeolite [100] , $LiClO_4$ [101], or $LiBF_4$ [102]. For the preparation of 3-(2-furfuryloxy)propionitrile by addition of furfuryl alcohol to the unsaturated double bond of acrylonitrile, the use of a strong basic catalyst has been patented [103]. In the presence of ethylene oxide, furfuryl alcohol can be ethoxylated to yield high-boiling, water-soluble ethers.

Hydrolysis. Levulinic esters can be prepared in high yield from furfuryl alcohol in dilute alcoholic HCl mixtures [104].

Levulinic acid

Pure levulinic acid can be obtained by subsequent hydrolysis of the esters. Methods for direct production of levulinic acid (4-oxopentanoic acid) from furfuryl alcohol have also been patented [105, 106]. Based on ^{13}C NMR spectroscopy a possible mechanism of levulinic acid formation from furfuryl alcohol has been proposed [70].

Hydrogenation and Hydrogenolysis. Metal-catalyzed hydrogenation of furfuryl alcohol can yield various products (Scheme 2). Of these, 2-methylfuran and tetrahydrofurfuryl alcohol are the most important compounds. In view of their economic importance, the production of tetrahydrofurfuryl alcohol and 2-methylfuran from furfuryl alcohol and other feedstocks is discussed in Chapters 5 and Chap. 8, respectively.

Open-chain compounds like 1,2- and 1,5-pentanediol are formed at elevated temperatures by hydrogenolysis of the furan ring with a Cu chromite catalyst [107, 108]. Low yields of 1,2,5-pentanetriol can be obtained in the presence of acid and a Raney Ni catalyst [109, 110].

Oxidation. Furfuryl alcohol can be oxidized to maleic anhydride and CO_2 in an O_2 flow over a V_2O_5 catalyst at 320 °C [111, 112]. Recent discoveries in oxidation chemistry have led to selective reactions for the oxidation of furfuryl alcohol to furfural [113, 114] and the versatile organic synthon 6-hydroxy-2*H*-pyran-3(6*H*)-one [115–118].

6-Hydroxy-2*H*-pyran-3(6*H*)-one

A titanium-substituted silicalite (TS-1) was reported for the heterogeneously catalyzed oxidation of furfuryl alcohol to 6-hydroxy-2*H*-pyran-3(6*H*)-one with H_2O_2 as oxidant [119].

Scheme 2. Hydrogenation of furfuryl alcohol

Halogenation. Furfuryl halides can be synthesized at moderate temperatures (0–25 °C) by use of $SOCl_2$, PBr_3, and PI_3 to obtain respectively furfuryl choride [120, 121], furfuryl bromide, and furfuryl iodide [122].

3.2. Resources and Raw Materials

Furfuryl alcohol is produced by catalytic hydrogenation of furfural.

For successful furfuryl alcohol production, a minimal furfural purity of 99.5 % is required. The maximum water content allowed is 0.2 wt % and the acidity should be below 0.02 eq/L. On vacuum distillation of furfural the solid residue should be less than 0.3–0.5 wt %.

3.3. Production

Hydrogenation of furfural to furfuryl alcohol with hydrogen is catalyzed by a reduced Cu catalyst. The composition of this catalyst is of utmost importance for selective hydrogenation of furfural without formation of side products or coke and without rapid catalyst deactivation. Furfuryl alcohol can be prepared from furfural by vapor-phase reaction or by liquid-phase reaction. Both routes are economically viable, though the vapor-phase reaction is currently most widely employed in industry. Reactions in the vapor phase are usually carried out at atmospheric pressure; hence, reactor investment is quite low compared with the high-pressure equipment needed for liquid-phase hydrogenation. On the other hand, vapor-phase hydrogenation uses high molar H_2/furfural ratios; hence, large amounts of H_2 must be circulated.

Liquid-Phase Production of Furfuryl Alcohol. Only small-scale manufacturers produce furfuryl alcohol by liquid-phase furfural reduction. The reactions are carried out in stirred tank reactors rather than in tubular plug-flow reactors.

The hydrogenation of furfural in the liquid phase was first reported in the patent literature by the Quaker Oats Company in 1928 [123]; a precipitated Ni on MgO catalyst was used. Because of subsequent hydrogenation of the aromatic ring, delicate process control was needed to prevent formation of tetrahydrofurfuryl alcohol (THFA). THFA formation could be circumvented by use of a precipitated Cu chromite catalyst at temperatures between 100 and 160 °C and H_2 pressures of 10–20 MPa. Under these conditions furfuryl alcohol yields of 95–98% can be obtained in solvent-free batch furfural hydrogenation. Reaction temperatures higher than 175 °C should be avoided in order to prevent formation of substantial amounts of resinous products and methylfuran. This method was patented by Rohm & Haas [124] and by Quaker Oats [125]. The selectivity of Cu-chromite-catalyzed hydrogenation can be further increased by addition of CaO to the reaction mixture to prevent acid-catalyzed resinification and etherification. With CaO, the reaction temperature can be increased to 180 °C without loss of furfuryl alcohol yield. At this high temperature an H_2 pres-

sure of 3 MPa is sufficient for successful hydrogenation; a furfural conversion and furfuryl alcohol selectivity of respectively 99.9 and 99.6 % were reported by Ashland Oil [126, 127]. Due to environmental considerations and costs associated with chromium salts, chromium-free Cu hydrogenation catalysts have been developed. CuFe on Al_2O_3 and Cu on ZnO or MgO proved to be efficient catalysts [128, 129].

Besides supported Cu catalysts, Ni-based catalysts have been recently reevaluated for furfuryl alcohol production. With Raney Ni impregnated with Mo polyacids [130, 131] and with Ni–P–B [132] or Ni–Fe–B amorphous alloy catalysts [133], THFA formation at high furfural conversion is significantly reduced in comparison with unmodified Ni catalysts.

The reaction heat for furfural hydrogenation is 63 kJ/mol. Particularly in a continuous fixed-bed reactor, special care must be taken to dissipate the heat. This can be achieved by diluting the catalyst bed with unreactive ceramics [134] or by diluting the furfural feed with furfuryl alcohol [128]. The kinetics of Cu-chromite-catalyzed furfural reduction have been reported [135].

Vapor-Phase Production of Furfuryl Alcohol. In all large furfuryl alcohol production plants, furfural is currently hydrogenated in the vapor phase. Gas-phase reduction of furfural on a supported Cu catalyst at 140 °C was first reported in 1927 [136]. The use of Cu chromite catalysts in the vapor-phase reaction was patented in 1931 by Du Pont de Nemours [137]. To compensate for the loss of activity of the Cu catalyst after a certain time on stream, the temperature of the catalyst bed is gradually increased. At temperatures between 155 and 180 °C, significant amounts of 2-methylfuran are produced. This problem was circumvented by Quaker Oats by the use of a reduced Cu on $Na_2O \cdot x\ SiO_2$ catalyst [138]. The use of basic sodium silicate lowers the hydrogenolysis activity towards 2-methylfuran, and furfuryl alcohol yields of 99 % are obtained in the temperature range between 132 and 177 °C. The $Cu/Na_2O \cdot x\ SiO_2$ catalyst can also be deposited on high surface area carriers [139, 140]. Use of Ca silicate instead of Na silicate leads to formation of basic oxides at the catalyst surface [141]. In the open literature, Pt catalysts on various supports have been reported for the vapor-phase reduction of furfural [142, 143].

Figure 5 presents the process diagram of a furfuryl alcohol production unit. Furfural is vaporized in a stream of hydrogen in a tubular vaporizer at 120°C (A). After demisting (B), this stream is superheated before it enters the oil-heated multitubular reactor (D). The liquid furfural from the demister pad is recovered in tank C. After passage through the reactor furfural conversion exceeds 99 %. The crude furfuryl alcohol is condensed from the reactor effluent and collected in tank E. The hydrogen stream is passed through another demister (F) before it is recycled to the vaporizer (A). Some of the hydrogen is continuously vented as a bleed stream to prevent accumulation of impurities. The crude furfuryl alcohol from tank E is reheated and distilled in a vacuum column (G) to obtain a furfuryl alcohol purity of more than 99 %. The bottom fraction of the vacuum column consists of high-boiling oligomers, whereas water and methylfuran are withdrawn from the top of the column.

A) Tubular vaporizer; B) Demister; C) Furfural recovery tank; D) Tubular reactor; E) Crude furfuryl alcohol tank; F) Demister; G) Vacuum distillation column; H) Vacuum pump; CW = cooling water

Production of furfuryl alcohol starts at a reactor temperature of 120 °C, which is maintained until furfural conversion drops below 99 %. To maintain the rate, the catalyst bed temperature is then gradually increased to 160–170 °C. For catalyst regeneration, the temperature of the reactor is increased to 220 °C and coke deposits are removed by oxidation. After pre-reduction at 160°C, the reaction with the Cu catalyst is restarted at 120 °C.

3.4. Uses and Economic Aspects

Uses. Furfuryl alcohol plays a vital role in the production of foundry sand binders (→ Tetrahydrofuran). For over thirty years it has been extensively used to produce high-quality cores and molds for metal casting. The major part of furfuryl alcohol is purchased by foundry binder suppliers.

Furfuryl alcohol is the major ingredient in furan foundry binders. Furan is a generic term for binders containing furfuryl alcohol and either urea or phenol–formaldehyde or mixtures of both. Today furfuryl alcohol is used in binders for furan hot-box, warm-box, and gas-hardened processes, and especially in the traditional Furan no-bake system.

The *furan no-bake process* was introduced in 1958. It is suitable for making all types of metal castings in all sizes, and is particularly used for the production of molds and larger cores. This acid-catalyzed cold-setting binder consists of hardening catalysts such as sulfuric acid, sulfonic acids, or phosphoric acid and a reactive furan-type resin which contains typically 75 wt % furfuryl alcohol. The furan no-bake process is known for its superior shake-out characteristics, and the sand can be reused by thermal and/or mechanical reclamation [144].

The *furan hot-box process* uses furan resins in combination with a latent acid catalyst. The *warm-box* process is operated at lower temperatures and was developed by the Quaker Oats Company for the rapid production of cores in existing hot-box equipment. The binder for this process contains more furfuryl alcohol than hot-box furan binders. A copper salt catalyst is used to cure the binder very rapidly on heating.

The *furan SO_2 process* is a gas-cured binder system for the rapid production of small molds and cores. Curing of the furanic resin occurs immediately when the sand mix is exposed to SO_2 gas at room temperature.

Apart from its use in foundry resins, furfuryl alcohol finds application in corrosion-resistant fiber-reinforced plastics, in corrosion-resistant cements and mortars, in wood protection [145, 146], as reactive solvent for phenolic resins in the refractory industry, in paint stripper and cleaning compound formulation, as chemical building block for drug synthesis (ranitidine), as viscosity reducer for epoxy resins, and as chemical feedstock for tetrahydrofurfuryl alcohol and 3,4-dihydro-2*H*-pyran.

Economic Aspects. Worldwide production of furfuryl alcohol increased significantly since the mid-1980s due to the great expansion of furfuryl alcohol production capacity in China. The largest furfuryl alcohol production plant is located in Belgium and produces 32×10^3 t/a. Smaller scale producers are located in Thailand and South Africa. In the USA production decreased fivefold since ca.1990. In 2003 wordwide production amounted to 133×10^3 t. Annual worldwide demand is estimated at (120–140) $\times 10^3$ t. Table 9 summarizes furfuryl alcohol production from 1987 to 2003 in Asia, South and North America, and Europe excluding the former USSR

3.5. Quality Specifications, Transportation, Toxicology

Quality Specifications. On the international market furfuryl alcohol and high-purity (HP) furfuryl alcohol must meet the specifications listed in Table 10.

Table 10. International market specifications for furfuryl alcohol and high-purity (HP) furfuryl alcohol

	Furfuryl alcohol	HP furfuryl alcohol
Furfuryl alcohol (GC assay), wt %	98.0 (min.)	99.0 (min.)
Furfural, wt %	0.7 (max.)	0.1 (max.)
Moisture, wt %	0.3 (max.)	–
Color, Gardner		1 (max.)
Cloud point, °C	10 (max.)	10 (max.)

Transportation. Furfuryl alcohol is shipped in steel or aluminum tanks or drums, ISO containers, and IBCs. All should be clean and must not contain any traces of acidic materials to prevent acid resinification of furfuryl alcohol, which can be violent. The use of hoses made of cross-linked polyethylene, fluorocarbons, ethylene–propylene rubber, or styrene–butadiene rubber is recommended for transferring furfuryl alcohol.

Containers for furfuryl alcohol storage need phenolic resin coating. Lacquer, vanish, and epoxy-resin coatings are not acceptable. Containers need to be tightly closed and stored away from open flames, acids, and strong oxidizers. The buildup of substantial concentrations of furfuryl alcohol in the atmosphere usually does not occur due to the relatively high boiling point (170 °C). Fires can be extinguished with water, foam, carbon dioxide, or dry chemical.

Toxicology. Furfuryl alcohol is harmful by inhalation, if swallowed, and in contact with skin. In case of acute overexposure furfuryl alcohol is irritating to eyes, skin, and/or respiratory tract. Furfuryl alcohol does not have genotoxic potential (in vivo); evidence of carcinogenic activity of furfuryl alcohol in rats is inconclusive.

LD_{50} values are 160 mg/kg (mouse, oral), 275 mg/kg (rat, oral), 400 mg/kg (rabbit, dermal) The LC_{50} has been determined as 592 ppm (rat, inhalation, 1 h). The occupational exposure limit is 10 ppm (8 h, TWA). The MAK value is 41 mg/m^3 (10 ppm). Furfuryl alcohol is readily biodegradable in aquatic environment. Detailed information on toxicity of furfuryl alcohol can be found in [147].

4. Furan

4.1. Properties

Physical Properties. Furan [*110-00-9*], furfuran, oxole, C_4H_4O, M_r 68.07, is a colorless

[c] Tag, open cup.

liquid with strong ethereal odor. It is low boiling and highly flammable. Some physical properties of furan are listed in Table 11.

Chemical Properties. Furan or oxole is the parent compound of the five-membered heterocycles containing one oxygen atom. The furan ring is a cyclic, fixed cisoid dienic ether and is stabilized by resonance. The aromatic properties of the furan ring are evident from its orbital structure. In the planar pentagonal structure each carbon atom has a single electron in its p orbital while the oxygen atom has electron pairs in p and sp^2 orbitasl. The electrons in the p orbital system form a delocalized 6π-electron system which gives the furan ring its aromatic character. The furan ring is less aromatic than benzene, as expressed in the respective resonance energies of 96 and 155 kJ/mol. In comparison with benzene and other heterocycles the aromaticity decreases in the following order.

The furan heterocycle is extremely susceptible to electrophilic aromatic substitution. Substitutions take place at the α- rather than at the β-position, as is evident from the resonance structures of the transition states. Hence, bromination, nitration, and alkylation yield respectively 2-bromofuran, 2-nitrofuran, and 2-alkylfurans.

If the furan ring is substituted with electron-donating substituents, electrophilic aromatic substitution reactions are accelerated. In the furan series the following reactivity towards electrophilic aromatic substitution is observed:

On heating in the presence of mineral acids furan and alkylfurans are hydrolytically opened to diketones. Furans with electron-withdrawing substituents are quite stable to hydrolytic cleavage.

At elevated temperature in the presence of steam and NH_3 or H_2S, furan and alkylfurans can undergo O/N and O/S exchange reactions leading to pyrrole and thiophene derivatives.

If the furan ring is not substituted with electron-withdrawing groups, it readily undergoes Diels–Alder reactions with activated dienophiles like maleic acid or anhydride.

Hydrogenation of furan to tetrahydrofuran is preferably carried out with a supported Ni catalyst. Supported noble metals like Ru and Pd, and to lesser extent Pt, catalyze both ring hydrogenation and ring hydrogenolysis reactions. The ratio between hydrogenolysis and hydrogenation products increases with increasing temperature.

Under mild oxidative conditions, e.g. with aqueous *m*-chloroperbenzoic acid (mCBPA) at room temperature, furan is oxidized to malealdehyde (or fumaraldehyde). At high temperatures in the presence of V_2O_5 or MoO_3 catalysts, furan is oxidized to maleic anhydride. These high temperature oxidations can also be carried out

with furoic acid, furfural, and furfuryl alcohol to produce maleic anhydride and CO_2.

Though the production of tetrahydrofuran via catalytic furan hydrogenation seems logical, this route is considered as less economical in comparison to tetrahydrofuran manufacture via maleic anhydride hydrogenation or the Reppe process. Nevertheless, furan hydrogenation to tetrahydrofuran has recently been reintroduced in China.

α-Acetylfuran, the precursor for the antibiotic Cefuroxime, is a common impurity in commercial furfural, but the costs for its recovery from crude furfural are economically prohibitive. a-Acetylfuran can be prepared by Friedel–Crafts acylation of furan with acetic anhydride. This reaction can be carried out in the liquid phase without solvent at 20–60°C with homogeneous catalysts like $ZnCl_2$ [148], H_3PO_4 [149], HI [150], and BF_3 [151]. In 1986 BASF patented the vapor-phase acylation of furan with Ce- and Cs-exchanged borosilicate zeolites. At furan conversions of 10–20 % selectivity for α-acetylfuran is up to 99 % at reaction temperatures of 150–200 °C [152].

2,2-Difurylpropane is obtained by electrophilic aroamtic substitution of furan with acetone.

2,2-Difurylpropane and 2,2-bis(tetrahydrofurfuryl)propane are currently used as rubber modifiers.

2,5-Dimethoxy-2,5-dihydrofuran, a versatile organic synthon, is prepared by bromine or chlorine oxidation of furan in methanol. If Na_2CO_3 is added to neutralize the produced HCl, a yield of 50 % can be obtained [153]. In the presence of Br_2, reported yields are somewhat higher [154]. Bromine or chlorine can also be generated in situ by electrolysis of an appropriate halide electrolyte. This results in the following overall reaction equation:

The yields obtained by electrolytic oxidation are generally in the range of 80–90 % [155–157]. Reduction leads to 2,5-dimethoxytetrahydrofuran, which can be used for the production of pyrrole derivatives [158].

Direct production of pyrrole from furan and NH_3 over a γ-Al_2O_3 catalyst in the presence of steam at 400 °C was published by Du Pont in 1952 [159]. Later patents by Japanese companies reported the use of alkali metal or alkaline earth metal exchanged amorphous silica alumina [160] or zeolites [161]. Exchanged zeolites are not only useful for pyrrole formation, but also for reaction of furan with H_2S to give thiophene [162–164].

4.2. Production

Furan is produced by Pd-catalyzed decarbonylation of furfural. It can also be manufactured by partial oxidation of 1,3-butadiene.

Decarbonylation of Furfural. Decarbonylation of furfural can be carried out via two catalytic routes. The oldest method is the decomposition of furfural into furan, H_2, and CO_2 in the presence of steam, catalyzed by Zn Fe or Zn Mn chromite [165, 166]. A Zn Fe chromite catalyst with a Zn chromite to Fe chromite ratio of 9:1 is reported to be the best performing material.

In a typical reaction, steam and furfural in a molar ratio of 1:5–1:10 are converted over the chromite catalyst at 400 °C with a GHSV of 500–1000 h^{-1}. Furfural to furan decarbonylation yields of more 90 % were claimed at total conversion of furfural. Addition of 1 wt % alkali

metal carbonate promoter to the catalyst matrix has a beneficial effect on the selectivity towards furan. Zn molybdite catalysts have also been reported to be active but furan yields are inferior in comparison with the chromite catalysts [167].

In 1959 Du Pont disclosed a Pd-catalyzed route to furan from furfural in the absence of steam. Furfural decomposes on the Pd surface to furan and CO.

In a typical procedure furfural is refluxed under pressure (200 °C) in the presence of a supported Pd catalyst in the presence of alkali metal carbonate. Furan and CO are continuously removed from the reaction mixture by distillation. A typical productivity of 4–10 kg of furan per gram of Pd can be obtained [168]. When the alkali metal carbonate is replaced with alkali metal acetate, the base-catalyzed resinification of furfural can be minimized [169]. Irradiative pretreatment (230–270 nm) of the Pd catalyst is reported to have a beneficial effect on the catalyst lifetime [170, 171]. The Pd-catalyzed decarbonylation can also be performed in the vapor phase [172]. In a typical example furfural is fed to a 0.3 wt % Pd on Al_2O_3 catalyst with a furfural WHSV of 230 h^{-1} in the presence of a molar furfural/H_2 ratio close to one. At 300°C, a typical furan yield of 95 % can be obtained. Typical productivities of 10–15 kg of furan per gram of Pd can be reached before the catalyst needs to be regenerated. By using supported Pt and Rh catalysts these productivities can be increased [173].

Partial Oxidation of 1,3-Butadiene. Partial oxidation of 1,3-butadiene in the vapor phase was first reported by Du Pont in 1957 with MoO_3 and WO_3 catalysts at 500 °C [174]. With the use of V–P oxide catalysts, 1,3-butadiene can be converted to furan in a yield of 7 % in the presence of steam and oxygen (1,3-butadiene GHSV of 100 h^{-1}, 480–590°C) [175]. Addition of promoters like Co, Ni, and Mo [176] and supporting the V P oxides on high surface area carriers results in more active catalysts [177]. Other catalyst compositions comprise Bi–Mo oxide on SiO_2 [178], Sb oxide promoted with Sn, Cu, and W [179], Ag Mo oxide supported on Al_2O_3 [180, 181], and Mo Bi Pb oxide promoted with Cu, V, and Au [182]. Yields of furan generally do not exceed 10–15%.

In 1987 Du Pont issued a low-temperature oxidation process (90–120 °C) for the production of furan from 1,3-butadiene. In this process 1,3-butadiene vapor is oxidized by $CuCl_2$ to furan in an aqueous mixture of $CuCl_2$, CuCl, NaCl, KI, and HCl. On total reduction of $CuCl_2$ to CuCl the 1,3-butadiene flow is interrupted and replaced by an oxygen flow to reoxidize CuCl. Consecutive production and reoxidation cycles render this process catalytic in Cu. Furan can be produced with high selectivity (90 %) at maximum 1,3-butadiene conversion of 20 %. Higher conversions and hence longer residence time result in extensive resinification of the produced furan. This catalyst composition can be used dissolved in an aqueous mixture [183–185] or supported on a solid carrier [186, 187]. Due to the extreme corrosiveness of the reaction mixture, reactors need a glass, carbon, or ceramic lining.

4.3. Uses, Economic Aspects, Transportation, Toxicology

Uses. Furan is mainly used in the preparation of specialty chemicals such as α-acetylfuran, 2,5-dimethoxy-2,5-dihydrofuran, 2,2-difurylpropane, 2,2-di(tetrahydrofurfuryl)propane, and pyrrole derivatives.

Transportation. Due to its low boiling point furan is a potentially hazardous chemical, and to prevent buildup in work areas should be properly vented. Drums or tanks containing furan must be earthed, able to withstand furan vapor pressure at ambient temperature, and stored away from oxidizers, strong acids, and heat sources. In the case of fire or explosion dry chemical foam or carbon dioxide should be utilized as extinguisher medium.

Toxicology. Furan is a narcotic, toxic substance that can be adsorbed though the skin and is suspected to be carcinogenic. LD_{50} (i.p.) values are 7 mg/kg for mice and 5.2 mg/kg for rats. The LC_{50} is 3464 ppm (rat, inhalation, 1 h).

5. Tetrahydrofurfuryl Alcohol

5.1. Properties

Physical Properties. Tetrahydrofurfuryl alcohol [*97-99-4*], 2-(hydroxymethyl)tetrahydrofuran, 2-tetrahydrofuranmethanol, THFA, $C_5H_{10}O_2$, M_r 102.13 is a transparent, mobile, high-boiling liquid with mild odor and is completely miscible with water. Physical properties of THFA can be found in Table 11.

Chemical Properties. Tetrahydrofurfuryl alcohol readily undergoes reactions typical of primary alcohols. Its saturated nature renders it quite stable towards mineral acids. However the tetrahydrofuryl ring can be cleaved by acetolysis or hydrogenolysis reactions. In the presence of $ZnCl_2$ and acetic anhydride, THFA is opened to 1,2,5-triacetoxypentane. Hydrolysis of this triacetate yields 1,2,5-pentanetriol [188, 189].

Hydrogenolysis of THFA can be effected by Cu chromite catalysts at high temperatures and pressures with a maximum 1,5-pentanediol yield of 35 %. This reaction is considered commercially uninteresting due to the extreme reaction conditions and only moderate diol yield [190, 191].

Dehydration of THFA to 3,4-dihydro-2*H*-pyran has been the subject of various patents in the last six decades. The reaction is always carried out in the vapor phase over an acid catalyst supported on alumina [192–198], or an alumina-doped acid oxide such as titania [193]. Reaction temperatures vary between 250 and 400°C with sometimes high yields of 3,4-dihydropyran; high temperatures tend to promote catalyst coking. The state of the art in THFA dehydration to 3,4-dihydro-2*H*-pyran can be found in Table 12.

Generally, simple tubular reactors are used, although a fluidized-bed reactor has been applied in one case [197]. Dilution of THFA vapors with a N_2 carrier generally increases 3,4-dihydro-2*H*-pyran yield. In recent patents, optimal operation temperatures are lower than 300 °C [197, 198]. The optimal catalyst composition in the latter patents is not mentioned, but it is likely that the γ-alumina support is loaded with acid metal oxides like MoO_3, TiO_2, or V_2O_5/P_2O_5.

3,4-Dihydro-2*H*-pyran is a key intermediate in the synthesis of 1,5-difunctional open-chain aliphatic compounds. With alcohols, tetrahydropyranyl ethers are formed under mild acidic conditions. These ethers are useful protecting groups for alcohols.

5.2. Production

Tetrahydrofurfuryl alcohol (THFA) can be produced directly from furfural or by the intermediate production of furfuryl alcohol. Supported Ni catalysts are preferred for both furfural and furfuryl alcohol hydrogenation. In early patents, Ni chromite was used for the production of THFA from furfural in the liquid phase, but yields were only moderate (ca. 65 %) [199–201]. With Raney Ni, THFA is formed quite selectively from furfural, but excessive operating pressures and temperatures are needed (25 MPa H_2, 150 °C) [202]. Production of THFA from furfuryl alcohol was patented by Quaker Oats in 1954 [203]. This patent described a vapor-phase process at 80 °C, in which furfuryl alcohol was completely and selectively hydrogenated to THFA by a Ni on kieselguhr catalyst. In today's industrial practice THFA is produced from furfuryl alcohol with various supported Ni catalysts. At moderate temperatures of 50–100°C both vapor- and liquid-phase processes are economically feasible.

5.3. Uses, Economic Aspects, Transportation, Toxicology

Uses. THFA is a water-miscible biodegradable compound and can be used as high-boiling solvent for dyes, printing inks, pesticides and herbicides, as paint-stripping agent, industrial cleaner, and reactive diluent for epoxy resins.

THFA is also used in the preparation of pharmaceuticals. Next to Nafronyl (a vasodilator)

Table 12. State of the art in THFA dehydration to 3,4-dihydro-2*H*-pyran

Patent	Catalyst	*T*	THFA feed	DHP yield
ICI, 1941 [192]	P_2O_5 (30 wt %) on alumina	350 °C	0.5 mL mL^{-1} h^{-1}	64 % at 98 % THFA conversion
Quaker Oats, 1959 [193][a]	TiO_2 (85–95 wt %) and Al_2O_3 (15–5 wt %)	320 °C	0.1–0.07 mL mL^{-1} h^{-1}, N_2 carrier	95 % at 97 % THFA conversion
Olin Mathieson, 1963 [194][b]	MoO_3 (10 wt %) on Alumina	367 °C	1.1 mL mL^{-1} h^{-1}, N_2 carrier	74 %
Olin Mathieson, 1963 [195]	V_2O_5 (10–20 wt %) on alumina	400 °C	1 mL mL^{-1} h^{-1}	56 %
Emery Ind., 1968 [196]	ε-alumina doped with oxides of Mo,V, and Ti	315 °C	6 g $g^{-1}h^{-1}$	90 %
BASF, 1995 [197][c]	γ-alumina doped with non-specified metal oxides	250 °C	0 g $g^{-1}h^{-1}$, N_2 carrier	77 %
BASF, 2001 [198]	γ-alumina doped with unspecified metal oxides	250 °C	0 34 g $g^{-1}h^{-1}$, N_2 carrier	92 %

[a] DHP yield was determined after distillation; molar ratio N_2/THFA=4.2.
[b] Molar ratio N_2/THFA=1.7.
[c] Fluidized-bed reactor, molar ratio N_2/THFA=9.8.

THFA is an intermediate for the preparation of disinfectants and antimetabolite drugs.

3,4-Dihydro-2*H*-pyran and to a lesser extent tetrahydrofurfurylamine (see Chap. 6) are the main applications of THFA in the production of specialty chemicals.

Transportation. THFA is shipped and stored in steel or aluminum containers. Due to its high solvent power, piping is preferably made of steel. If ignited, fire can be extinguished by alcohol foam, CO_2, and dry chemical diluted with water spay. THFA must be stored away from open flames, strong acids, and oxidizers.

Toxicology. THFA is water-soluble, biodegradable compound with an atmospheric half-life of 13 h. Oral LD_{50} in rat, mouse, and guinea pig are respectively 1600, 2300, and 800 mg/kg. The LD_{50} (i.p.) for rats and guinea pigs is 400 mg/kg.

6. Furfurylamine and Tetrahydrofurfurylamine

Furfurylamines are produced by reductive amination of furfural. Supported Ni catalysts [204–206], Raney Ni catalysts [205, 207, 208], and supported Co catalysts [206] have been found to be effective for this reaction. When furfural is contacted with NH_3 the imine is formed. Furfurylimine (**12**), which is unstable, readily undergoes a condensation reaction to give the trimeric hydrofuramide (**13**). Hydrogenation of hydrofuramide yields difurfurylamine (**14**) and furfurylamine (**15**). Undesired formation of difurfurylamine can be avoided by using an excess of NH_3, by using primary amines as cosolvent, or by gradual admission of furfural during reaction. On heating, hydrofuramide is converted to furfurine (**16**). Furfurine is a stable unwanted byproduct which cannot be converted to amines by hydrogenation. If the reductive amination is carried out at temperatures higher than 110 °C, furfurylamines are converted to tetrahydrofurfurylamine (**17**) [209].

Direct production of tetrahydrofurfurylamine from tetrahydrofurfuryl alcohol with a Raney Ni catalyst has also been reported [210].

At 210 °C and 6 MPa H_2 pressure, piperidine can be formed from furfurylamine or tetrahydrofurfurylamine by using a Co–Re–Mo catalyst [211, 212]. In the case of tetrahydrofurfurylamine conversion and piperidine selectivity exceed 90 %.

Furfurylamine and tetrahydrofurfurylamine are high-boiling colorless to pale yellow liquids with typical amine odor. Physical properties of these compounds are listed in Table 11.

Furfurylamine and tetrahydrofurfurylamine find application in the synthesis of herbicides, pesticides, pharmaceuticals, and piperidine derivatives. Furfurylamine is a key intermediate for the production of the diuretic furosemide. An LD_{50} of 200 mg/kg (i.p., mouse) is reported for both furfuryl and tetrahydrofurfurylamine.

7. Methylfuran and Methyltetrahydrofuran

2-Methylfuran or sylvan is a common byproduct in the vapor-phase production of furfuryl alcohol from furfural. In this process the Cu or Cu chromite catalysts are slowly deactivated by coking during furfural production at low temperature (130 °C). To maintain the same production rate the reactor temperature is gradually increased to 150 or 160 °C, at which 2-methylfuran is produced by hydrogenolysis. This is the only source of 2-methylfuran in the chemical industry.

Though 2-methylfuran is currently made as a byproduct of furfuryl alcohol manufacture, several attempts have been made towards selective 2-methylfuran production from furfural [213–215] and furfuryl alcohol [216, 217]. Most attempts have focused on the use of Cu chromite catalysts at elevated temperatures (175–200 °C). At these temperatures the catalyst is rapidly deactivated, and this prohibits the commercial implementation of these processes.

2-Methyltetrahydrofuran is produced by Ni-catalyzed hydrogenation of 2-methylfuran. This reaction can be performed in the liquid phase under H_2 pressures of 2 MPa or in the vapor phase at atmospheric pressure with common supported Ni catalysts.

In the future 2-methyltetrahydrofuran could also be produced by cyclization and hydrogenation of levulinic acid.

A method was patented for the single-stage production of 2-methyltetrahydrofuran from levulinic acid with a Re/Pd on carbon catalyst [218]. Though these processes have not been brought to industrial practice they hold the potential for the use of hydrolyzed C_6 carbohydrate biomass (i.e., a potential source of levulinic acid) for the production of base bulk chemicals ([218] and references therein).

2-Methylfuran and 2-methyltetrahydrofuran are both colorless mobile liquids with high solvent power. Some of their physical properties are listed in Table 11. 2-Methyltetrahydrofuran is inversely soluble in water, i.e., the solubility decreases with increasing temperature. The chemical properties of 2-methylfuran and 2-methyltetrahydrofuran are comparable to those of furan and tetrahydrofuran, respectively. 2-Methylfuran is used as solvent and as feedstock for the production of antimalarial drugs (chloroquine), methylfurfural, nitrogen and sulfur heterocycles, and functionally substituted aliphatic compounds. 2-Methyltetrahydrofuran is mainly used as a higher boiling substitute for tetrahydrofuran as specialty solvent. 2-Methyltetrahydrofuran can also be used in the electrolyte formulation for secondary lithium electrodes [219] and as a component of alternative fuels [220].

2-Methylfuran and 2-methyltetrahydrofuran are both hazardous highly flammable liquids and should be handled with the same precautions as furan and tetrahydrofuran, respectively. LC_{50} values are 500 ppm (rat, inhalation, 4 h) for 2-methylfuran and 6000 ppm (rat, inhalation, 4 h) for 2-methyltetrahydrofuran. The LD_{50} of 2-methyltetrahydrofuran is 4500 mg/kg (rabbit, dermal).

8. Furoic Acid

Furoic acid can be produced by the Cannizzaro reaction or oxidation of furfural. In the Cannizzaro reaction of furfural, furoic acid salts and furfuryl alcohol are formed in equimolar amounts. When sodium hydroxide is used as base, sodium furoate crystals partially precipitate during the reaction. After filtration and acidification of these salts, crude furoic acid is purified by sublimation. Though the maximum theoretical furoic acid yield is 50 % and product purification is difficult due to the presence of furfuryl alcohol and resinous material, furoic acid is still produced by this route today.

Furoic acid
2-Furancarboxylic acid

In the past, selective oxidation of furfural with molecular oxygen or hydrogen peroxide has been investigated. High yields of furoic acid (salts) can be obtained with these oxidation processes, but they have not been implemented for large-scale furoic acid production.

In the presence of catalytic amounts of silver oxide and oxygen high yields (95 %) of furoic acid salts were reported for the oxidation of furfural in strongly alkaline media. Furoic acid is then obtained by acidification of the salts with H_2SO_4 or HCl. The difficult removal and reactivation of the silver catalyst are the major drawbacks of this method [221, 222]. The Quaker Oats Chemical Co. expanded the use of Ag catalysts to Au, Pt, and Pd and supported these noble metals on metal oxides like Fe_2O_3 [213, 223]. A bimetallic Pt/Pb on carbon catalyst has also been reported for the efficient selective oxidation of furfural to furoic acid with molecular oxygen in aqueous alkaline media [224]. The process issued by Interox Chemicals features biphasic oxidation of furfural with a concentrated aqueous solution of hydrogen peroxide in the presence of a secondary or tertiary amine [225].

Furoic acid can be converted to furoyl chloride, which is used in drug and insecticide manufacturing. Its esters can be produced by common esterification reactions. Tetrahydrofuroic acid is produced by hydrogenation of furoic acid or by hydrogenation and hydrolysis of furoic esters. Methyl furoate and methyl tetrahydrofuroate are used as intermediates for cardiovascular and cancer drugs. Furoic acid is a precursor for synthesis of antibiotic, alpha blockers, and corticosteroid intermediates.

Physical properties of furoic acid are listed in Table 11. Furoic acid has a LD_{50} (i.p., mouse) of 100 mg/kg.

1. Introduction

1.1. Definitions

This article surveys the chemical and physical treatment of fur skins from the raw material to the dressed and finished individual furs. The term *fur dressing* (Chap. 3) describes operations (e.g., soaking, washing, tanning, and fatliquoring) that do not significantly change the hair of the fur skins. The term *fur finishing* (Chap. 4) encompasses processes (e.g., bleaching, dyeing, and mechanical operations) that modify the appearance of the hair.

1.2. Fur-Bearing Animals

The raw materials used for the manufacture of leather are mainly large skins and hides of domestic mammals (e.g., cow, calf, sheep, pig, and goat). For the production of furs, however, the skins of more than one hundred different species are used. These animals are almost exclusively mammals and include cloven-hoofed animals, predators, and rodents. The economic significance of the various fur skins varies widely (Chap. 6).

In order to meet steadily growing demand, valuable fur skins, e.g., sable, chinchilla, mink, fox, and karakul (Persian lamb), are obtained mainly from animals bred in captivity. Fur skins obtained from animal farms are usually more valuable than the corresponding skins obtained from the wild. Animal farms now account for 90 % of fur skin production.

1.3. Technological Data

The countries in which fur skins are dressed and finished on an industrial scale are mainly those with a large production or consumption of such skins. Fur skins are often dressed and finished on a commission basis. From prehistoric times, dressing and finishing have been carried out in aqueous solutions of certain chemicals. The vessels most frequently used for wet treatment are *paddles,* large trough-like containers with a paddle in which the fur skins float in long dilute liquors; the chemicals are only incompletely taken up. For reasons of economy (to save time, and to reduce consumption of energy, water, and chemicals) and to reduce environmental pollution, equipment used in leather production has been introduced, e.g., tanning drums (often specially equipped) and other machines based on the same principles as drum washing machines (but with Y-shaped partitions) or cement mixers (→ Leather).

The term *liquor ratio* denotes the ratio of the volume of liquor to the weight of fur skin. In processing raw, dried pelts in paddles, the liquor ratio may vary between 12 : 1 and 30 : 1;

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a12_135

for moisture-containing, centrifuged fur skins, it may vary from 5 : 1 to 10 : 1; and in drums from 3 : 1 to 6 : 1. The amount of chemicals used is usually expressed in g/L, mL/L, or sometimes as a fraction (wt %) of the weight of the fur skins.

2. Nature and Production of Fur Pelts

2.1. Morphology

Morphologically, there is essentially no difference between the skins and hair of animals that are processed for leather and those that are used for fur skins (→ Leather). The corium or true skin of some fur-bearing animals, e.g., chinchilla, is thin, whereas in other species, such as the seal, the corium is very thick.

The *hair* of many different types of fur skins varies widely in form and structure, and is species-specific. Even the hair of an individual skin does not have a uniform structure. There are three different kinds of hair:

1) Guard-hair, which is long, smooth, straight, and relatively sparse
2) Top-hair, which is also straight, somewhat shorter than the guard-hair, and thicker in the center
3) Underhair, underwool, fur-hair, or underfur, which is short, silky, usually crimped, and far more numerous than the other types of hair; lamb- and sheepskins possess only this type of hair.

Hair is a product of the thin outer layer of the skin, the epidermis. In the production of leather, the hair and the outer layer are removed by liming. (For details of the fine structure of hair, see → Hair Preparations, → Wool.)

2.2. Flaying

The pelt should be stripped from the animal carcass as soon as possible, but not before the body has cooled and bleeding stopped. The skins and hides used for the production of leather, and also the pelts of larger species, e.g., sheep, beaver, seal, and the big cats, are almost always flayed in the flat form. In contrast, the smaller types of pelt are cased: the skins are cut on the under side of the tail and along the hind legs across the body, and the skin is then removed by pulling it over the head of the body like a glove. The latter method is easier to carry out and is also beneficial for the fur.

2.3. Preservation

Freshly flayed fur pelts are seldom processed immediately. In most cases they are preserved; the water content of the skin is reduced in order to prevent putrefaction by microorganisms.

The customary method of preservation is to dry the skin in air at a not too high temperature (ca. 25 °C, with some air convection) and in a lightly stretched state. The hair itself is resistant to microorganisms, but if the skin begins to putrefy owing to inadequate or careless preservation bacterial destruction of the hair roots causes the hair to become loose, so that the complete fur skin becomes worthless.

The method of preserving the skins by salting, or by salting followed by drying, is used only for the skins of large fur-bearing animals in the flat form. Common salt is used to remove moisture from the skin, inhibiting putrefaction. Storage of the fur skins in cold rooms or cold storehouses hinders development of microorganisms and also protects the skins from attack by pests such as grease beetles and moths.

3. Fur Dressing

3.1. Soaking

The object of soaking is to moisten the preserved skins thoroughly, returning them to the condition in which they were immediately after flaying. The soak also removes dirt, blood, and preserving salt as well as water- and salt-soluble proteins. The pelts are soaked in water at 15 – 25 °C in vats, paddles, or drums, depending on the sensitivity of the raw material. Salted skins are generally more readily wetted than dried skins. Small amounts of bactericides are usually added to the soaking baths, and in wetting dried skins, common salt, and surfactants are added to accelerate the soaking process.

3.2. Scouring

Dirty and very greasy skins, particularly those of lamb and sheep, are given one or two washes at 25 – 35 °C in paddles or drum washing machines. The detergents commonly used for scouring fur skins are mixtures based on alkyl ether sulfates and alkyl sulfates with nonionic alkyl(phenyl)polyglycol ethers. Fat-dissolving organic solvents and soda are often added to the wash baths. The amount of detergent used is 1 – 3 g/L, and the maximum washing time is 2 h. Scouring is followed by rinsing, draining, and centrifugation or partial removal of water by passing the fur skin between rollers (*samming*).

3.3. Mechanical Treatment

After scouring, the rinsed skins are fleshed, i.e., freed from subcutaneous tissue and residues of flesh and fat. This process is carried out either manually on the fur dresser's bench or mechanically on fleshing machines. The smaller fur skins are shaved with a circular knife to level the thickness of the leather and to reduce the weight.

3.4. Pickling

Before the actual dressing process (tanning), the fur skins are pickled. The pickling serves several purposes: to loosen and open up the collagen of the skin by the hydrolytic effect of an acidic salt solution, to remove soluble protein, and to prepare the leather part for the subsequent dressing with mineral tannins.

The most common pickling acid was sulfuric acid, but as it is liable to damage the leather, it has now been replaced largely by organic acids, e.g., formic [*64-18-6*], glycolic [*79-14-1*], lactic [*598-82-3*], or sulfophthalic acid [*26657-75-0*], and also certain short-chain dicarboxylic acids. The concentration of the acid or the acid mixture in the pickle is 3 – 10 g/L. In order to prevent any acid-induced swelling of the collagen, and according to the type of pickling acid used, 40 – 80 g/L of common salt is added to the pickling liquor before immersing the fur skins. The temperature of the pickling bath is 20 – 30 °C, and the pickling time is usually 12 – 48 h. The fur skins are normally pickled in paddles or drums.

3.5. Tanning

Tanning converts the skin or hide substance of the pelt into leather. Tanning causes the peptide chains of the collagen to become differentiated or isolated from each other, cross-linked, and thereby strengthened; tanning markedly raises the shrinkage temperature. (For the theory of tanning, see → Leather.)

Fur skins must not be made heavy and leathery by the tannage; almost no vegetable tannins and few synthetic tanning agents are used.

Leipzig dressing is the oldest method of dressing and was once common; it consists merely of a common salt and sulfuric acid pickle, followed by oiling. Leipzig dressing cannot claim to be a tannage in the real sense of the word. Although it produces a lightweight and elastic leather that can be readily processed, the water resistance and the storage stability are quite unsatisfactory.

Dressing with Aluminum Salts. One of the oldest methods of dressing fur skins, still often used, is treatment with ammonium [*7784-26-1*] or potassium aluminum sulfate [*7784-24-9*], and aluminum sulfate [*7784-31-8*]. Solutions of these salts (applied in amounts of 20 – 50 g/L at ca. 30 °C) produce white and fairly elastic leathers, but the water resistance is unsatisfactory. During tanning, free acid is formed by hydrolysis; it is therefore necessary to add common salt to the tanning float to prevent acid-induced swelling of the collagen. At the end of the tanning process, the liquor is adjusted to a pH of 3.8 – 4 (preferably with sodium acetate). Chlorides and nitrates are superior in tanning behavior to the much more acidic sulfate salts of aluminum. The former are less readily washed out and they have greater tanning activity. The chlorides are often stabilized with masking agents and placed on the market as prepared tanning salts.

Trade Names: Lutan (BASF), Pellutax (Henkel), Novaltan (Zschimmer & Schwarz).

In order to improve the water resistance of the leather, accelerate leathering, and raise the shrinkage temperature, the use of aluminum salts in dressing is often combined with formaldehyde [*50-00-0*] or chromium salts.

Dressing with Aldehydes. Formaldehyde alone is rarely used for tanning because it produces fur skins that are very flat, that have poor stretch, and that are liable to lose tensile strength during storage. Formaldehyde is often used, however, in combination with other tanning and fatliquoring agents.

Dressing with Chromium Salts. In contrast to dressing with aluminum salts, tanning with chromium(III) salts is irreversible. Tanning or retanning with chromium salts produces a leather that has good resistance to water and heat, but somewhat inferior elastic properties. This method of tanning is indispensable whenever the fur skins are to be dyed with synthetic dyes (cf. Chapter 4.3). Chromium salts cannot be used, however, for fur skins that are to be dyed in dark shades with oxidation dyes or that are to undergo an oxidative bleach, because this would result in damage to or complete destruction of the leather.

The products used for chrome tanning of fur skins are the same as those recommended for the production of leather.

Trade Names: Chromosal (BAYER), Chromitan (BASF) Salcromo (STOPPANI), Chromodul (BRITISH CHROME).

For details of the theory of chrome tanning, basicity, masking, etc., see → Leather.

Chrome dressing is carried out with 5 – 15 g/L of chrome tannin (with a chromium oxide content of 25 – 30 %) together with common salt at 30 – 35 °C. The exact amount of chrome tannin used depends on the specific fur skin, the treatment that it has already received, and the shrinkage temperature desired. The tanning process, which takes 12 – 24 h, commences with low-basic chromium salt solutions and the bath is subsequently basified moderately by slow addition of solutions of weak alkali. After the dressing, the fur skins are drained and then centrifuged or partially dried.

3.6. Oiling and Fatliquoring

The purpose of oiling or fatliquoring is to render the leather of the fur skin soft and supple. During this process, the skin fibers are enveloped with fatty material to prevent them from sticking together during drying. Certain types of fur skins are treated for this purpose with water-insoluble fats in hammer or faller (crank) stocks. Fatliquoring is carried out with oiling agents emulsified in water. The starting materials for these products are in most cases liquid derivatives of animal and vegetable, nondrying oils, and also synthetic products (higher molecular mass chlorinated hydrocarbons). The natural oils are rendered emulsifiable in water by being partially sulfated or sulfonated, the synthetic substances by partial chlorosulfonation followed by saponification. In many cases medium viscosity mineral oils are also added to the fatliquors.

Fur skins can be oiled or fatliquored at all stages of processing and by various techniques. The oldest method is *brush oiling;* the oiling agent is applied with a brush to the leather side either manually or by machine. A growing trend is the application of electrolyte-stable fatliquors (in amounts up to 15 g/L) either in the tanning bath or immediately after tanning. If the fur skins are not to undergo any further wet treatment, fatliquoring is followed by drying at ca. 35 °C, depending on the relative humidity and the amount of air movement.

3.7. Degreasing in Organic Solvents

Degreasing removes fatty matter and solvent-soluble substances from the hair and the leather, thus reducing the weight of the fur skins. Degreasing also improves the dyeing properties, e.g., for suede. The customary method is to treat dry fur skins, dyed or undyed, dressed with mineral tannins, in degreasing machines for a few minutes at 20 – 30 °C with solvents (chlorinated hydrocarbons or fluorohydrocarbons). After degreasing, and in some cases refatliquoring, the fur skins are centrifuged in the machine and dried. Complete degreasing is never intended; on the contrary, a certain amount of fat should always remain in the leather. In order to ensure this, fatliquoring during the dressing process is carried out with a large proportion of nonextractable substances.

4. Fur Finishing

4.1. Bleaching

Reductive Bleach. Naturally white, but slightly yellowed fur skins of sheep and lamb, and certain types of kid and rabbit skins for which a pure white shade of hair is highly desirable but impossible to achieve simply by washing, are usually given a reductive bleach. The skins are treated during or after the wash (or for chrome-tanned skins also in the neutralizing bath) with sulfites, bisulfites, or most commonly with dithionite. Bleaching is carried out with 3 – 10 g/L of these products for up to 24 h at 25 – 35 °C. In order to achieve an exceptionally good effect, the reductive bleach may be preceded by an oxidative bleach with hydrogen peroxide (→ Bleaching, Chap. 2.2.4.).

Oxidative Bleach. A real bleach in the sense of an intensive destruction of the natural pigments in the hair can only be achieved by means of an oxidative bleach with peroxides, e.g., hydrogen peroxide, or persulfates, catalyzed by iron(II) salts; this treatment destroys the pigments in the hair. This method, or one of its numerous variations, is used to bleach the hair of naturally dark skins, e.g., black karakul or muskrat, in order to dye them subsequently in fashionable shades. For the catalytic bleach, the fur skins must be in faultless condition and must not have undergone any chrome tannage.

The catalytic bleach is a very difficult process to control and must be monitored carefully; the bleaching conditions (type and amount of chemicals, time, temperature, and pH) must be controlled precisely. A reductive afterbleach is often given in order to remove the iron salts. Following the bleach, the fur skins are retanned and in most cases fatliquored or oiled.

4.2. Dyeing

General. Although many types of fur skins, particularly the more valuable furs, are further processed without dyeing, the proportion of skins that is dyed has increased markedly in recent years (e.g., sheepskin articles for decorations, automobile seat covers, and clothing).

There are many variations in the process of fur dyeing, and the method used depends on the kind of fur. Certain types of fur skins are dyed only lightly in the hair and the leather by means of a bath treatment (*blending:* adjustment of natural shades; *reinforcing:* to intensify natural colors by treatment with metal salt solutions; or *blueing:* treatment of naturally yellowish fur skins with small amounts of blue dye) or only dyed partially in the hair by a brush or spray process (*tipping:* application of dye to the tips of guard hairs; *striping:* application of a dye solution to the central, or dorsal, region of certain fur skins in order to imitate a natural darkness in that region). The dull shade of naturally black karakul is intensified by bath dyeing, which simultaneously promotes gloss. The cheaper furs, such as lamb, sheep, kid, and rabbit, can be made to look like valuable furs by suitable dyeing and mechanical treatment. These cheaper fur skins are also printed to produce imitations of more valuable fur skins.

The presence of different types of hair, and variations in the chemical composition and morphology of the hair and skin, exerts a marked influence on the different behavior of the two proteins keratin and collagen in the dyeing process.

The keratin of the hair contains the same amino acids as the collagen of the skin, with the exception of L-hydroxyproline [*51-35-4*]. In contrast to collagen, keratin contains cysteine [*52-90-4*], which cross-links the polypeptide chains of the keratin and imparts stability. In addition, the proportion of acidic amino acids in keratin is far larger than in collagen. Consequently, the isoelectric points of the two polypeptides, an important factor for dyeing, lie at different pH; for untreated collagen, it is at ca. pH 7, whereas for keratin it is at ca. pH 5.5. Apart from this, the isoelectric point of collagen is shifted by tannage, whereas that of keratin remains practically unchanged (except when the skins are treated with aldehydes).

In order to accommodate these phenomena, certain rules have been established for dyeing fur skins. A dyeing temperature higher than 60 – 70 °C cannot be used because of the limited hydrothermal resistance of the leather. As both the hair and the leather are affected by alkali, dyeing cannot be carried out at high pH. Dyed skins must have a level surface and satisfactory

fastness to light, rubbing, and sublimation; in many cases dyed sheepskins are also required to have good fastness to ironing (see Chap. 5).

Pretreatment.

Killing. The purpose of killing is to clean the hair and open it up to take up the dye by spreading out the scales. The chemicals used for killing include ammonia, soda, or (less often) caustic soda solution together with wetting agents or detergents. The intensity of killing depends on the type of fur skin and the color effect desired. The brush process or the dip process may be used for this purpose. Dip killing takes 1 – 3 h at 20 – 35 °C.

Mordanting. Before dyeing with oxidation dyes the fur skins are treated with metal salt solutions, usually potassium dichromate or iron(II)sulfate, or (less often) copper(II)sulfate, or mixtures of these products. These mordants convert the dyes into color lakes and thus improve their fastness and the depth of the dyed shade. The mordants act on the killed and thoroughly rinsed fur skins in weakly acid solution; they must penetrate into the hair to ensure that the lacquer is adsorbed in the interior of the hair. Each mordant imparts a characteristic shade to the color lake. Mordanting is usually carried out in baths at 25 – 30 °C with 0.5 – 3 g/L of potassium dichromate or 3 – 6 g/L of iron(II)sulfate, and the process usually takes several hours. Adjustment of the pH, an important factor, is effected with formic, acetic, or tartaric acid or with potassium monotartrate (in amounts of 0.5 – 2 g/L). In most cases the mordanted fur skins are merely centrifuged or sammed (partially dried by rollers).

4.3. Fur Dyes

Vegetable Dyes. The oldest method of dyeing fur skins was to treat them with extracts of logwood, red wood, fustic, or sumach leaves. This method is seldom used today; it is restricted almost exclusively to the black dyeing of karakul with logwood and iron or copper salts. This dyeing process is complicated and usually has to be repeated several times; between the treatments, the fur skins are hung up in humid rooms at ca. 30 °C to ensure satisfactory oxidation of the dye.

Oxidation Dyes (→ Azine Dyes, Chap. 2.2.6.). These colorants were placed on the market towards the end of the last century and are still commonly used. They are not strictly dyes, but chemicals from which a pigment is formed in the hair by oxidation and conversion with metal salts. Examples of oxidation dyes include 1,4-phenylenediamine [*106-50-3*], pyrocatechol [*120-80-9*], resorcinol, aminophenols, and analogous naphthalene derivatives.

Trade Names: BASF Ursol (BASF), Nako (HOECHST).

Oxidation dyes produce dull colors from yellow to orange, brown, blue-grey and grey, to black with good levelness, and in full shades with good lightfastness, on all types of fur skins; the fastness to ironing is only limited.

The dye bath is prepared in a paddle at 30 – 35 °C, and the mordanted fur skins are then added. The dye (up to 8 g/L) is added with approximately the same amount of 30 % H_2O_2, usually in several portions. The actual pigment dye is developed in the course of several hours.

Fur skins that have been dyed with oxidation dyes must be washed and rinsed thoroughly to remove all loose and incompletely oxidized dye. Since the various bath treatments and rinses remove much of the tanning and fatliquoring agents from the fur skins, they are usually tanned and oiled or fatliquored again after dyeing. In working with oxidation dyes, certain precautions have to be taken because some people are allergic to specific products.

Synthetic Dyes. The large number of synthetic dyes, together with the use of new technology for dyeing the hair of fur skins, has now made it possible to meet demands for furs dyed in fashionable shades. Synthetic dyes are only taken up by the material at elevated temperature: for this reason, the fur skins must be chrome tanned or chrome retanned, so that the shrinkage temperature is at least 20 °C higher than the dyeing temperature of 60 – 65 °C. With these dyes, it is possible to dye the whole range of shades relatively easily by the bath process and in a far shorter time (1 – 2 h) than that necessary for dyeing with oxidation dyes. No mordant is required and killing is far less intensive; it is actually a hair cleaning rather than a killing process.

Disperse Dyes. Disperse dyes are azo and anthraquinone dyes, e.g., Cellitone (BASF), which, with the aid of dispersing agents, yield colloidal solutions in water (→ Disperse Dyes, Chap. 1.). They can be combined with one another, and they are taken up by the material at a temperature of less than 60 °C. Disperse dyes produce level dyeings in pale to medium shades with a medium level of lightfastness, but their fastness to ironing is unsatisfactory. These colorants are very suitable for use as brightening dyes in combination with oxidation dyes and as blending dyes for valuable fur skins.

1 : 2 Metal-complex dyes are also used in fur dyeing; for more details, see → Metal-Complex Dyes. When applied to lamb- and sheepskins at a minimum of 60 °C, these dyes produce shades with highly satisfactory fastness to light and ironing. They can be combined with one another (in amounts up to 2 g/L). With the aid of carriers (certain ethoxylation products and emulsions of chlorobenzenes or esters of phosphoric acid) they can also be used for dyeing dark shades.

Trade Names: Eukesolar (BASF), Irgalan (Ciba-Geigy), Dermalicht (Sandoz).

Anionic Dyes. From the comprehensive range of anionic dyes used in the textile and leather industries, only a few simple nitro, monoazo, and anthraquinone dyes have established themselves for dyeing the hair of fur skins (→ Azo Dyes, Chap. 3.). They are mainly low molecular mass dyes, which stain the leather only lightly or can be stripped from the leather by reduction, and are readily miscible with each other.

Anionic dyes often have unsatisfactory lightfastness when applied in pale shades. They are used on a fairly large scale as mixtures on the principle of trichromatic dyeing for dark shades.

Trade Names: Lurazol (fur) (BASF), Sellacid (Ciba-Geigy), Dermapelz (Sandoz).

Additions, Drying. The dyed fur skins are washed and rinsed, and if necessary tanned and fatliquored again.

As all treatments carried out in baths are liable to damage the hair of fur skins, it is customary to add fiber protective agents based on protein degradation products: these shorten the treatment by virtue of their surface action and function as protective colloids. For protection against the attack of moths, the fur skins may be treated in the bath with preparations such as Eulan (Bayer).

All wet treatments are usually followed by mechanical removal of water from the skins and drying at moderate temperature.

4.4. Special Dyeing Processes

Suede. Tone-in-tone dyeings (with the wool and the leather dyed in the same shade) can be produced by first dyeing the wool with oxidation dyes and then the leather with special leather dyes (→ Leather). When the hair is first dyed at elevated temperature with synthetic dyes, the leather is usually dyed in a fresh bath after the fur skins have been neutralized and rinsed.

For suede with white wool the intermediately dried, buffed skins are treated with a wetting agent and then dyed at room temperature with selected leather dyes that do not stain the wool at such a temperature.

Printing of Fur Skins. Imitations of valuable furs, such as leopard, ocelot, or tiger, can be produced on fur skins that have been suitably treated, in most cases lamb, sheep, calf, or horse, by the printing methods used in the textile industry. The printing inks most commonly used are solutions of oxidation dyes that contain a thickening agent and hydrogen peroxide.

Resist Process. Two-color effects can be produced on lamb- or sheepskins by brushing the hair with solutions of certain plastics at the parts that are to be resisted. The resist paste is allowed to dry, the fur skins are dyed in a hot bath, and the resist paste is then removed by rinsing with cold water.

5. Mechanical Operations

In addition to the chemical processes discussed above, certain mechanical operations also play a critical role in the dressing and dyeing of fur skins.

Drumming and Cageing. In this important operation, the dressed or dyed fur skins are tumbled in batches in large drums for several hours with moist, later with dry, sawdust from

deciduous trees (beech, poplar, or birch). This operation removes excess fat, salts, and other impurities, and improves the suppleness of the leather and the gloss of the hair. In addition to water, organic solvents (tetrachloromethane or tetrachlorethylene) and surfactants may be added to the sawdust. After this treatment, the adhered dust and shavings are shaken out of the fur skins using a rotating drum similar to the drum used for cleaning, but which consists of a wide-meshed wire cage.

Stretching and Staking (→ Leather). These operations render the leather softer and more elastic.

Plucking or Dehairing. Certain kinds of fur skins, e.g., nutria, beaver, and rabbit, have top-hair which often has to be removed, either by hand with special instruments or on plucking machines.

Shearing. Special effects can be obtained on some types of fur skins, e.g., sheep, lamb, rabbit, and nutria, by trimming the hair on shearing machines.

Ironing. The wool of sheep and other skins with dull and crimped hair can be stretched and made more lustrous by ironing on machines provided with heated, rapidly rotating cylinders. The hair is brushed with water, with or without the addition of a wetting agent, and the hair side is then ironed at ca. 200 °C, and the process repeated several times. In order to fix the stretching effect on the hair and to make the effect resistant to moisture, the ironing solutions applied later contain increasing amounts of formaldehyde together with water-soluble alcohols and acid. This process can be used, for instance, to produce imitations of beaver on lamb skins.

Beating and Combing. The hair of the dried skins is finally beaten and combed, either by hand or mechanically, in order to eliminate felting.

Sorting. The final sorting of the fur skins according to the kind of fur, color, general appearance, fall and fineness of the hair, appearance of the curls, and the size is an operation that requires considerable experience.

6. Economic Aspects

The main suppliers of valuable fur skins are the former Soviet Union, Scandinavia, and North America. Annual production in 1983/84 is given in Table 1.

Table 1. World production of fur skins in 1983/1984

Fur	Country	Approximate number of skins, $\times 10^6$
Mink	Soviet Union	9
	Scandinavia	13
	United States	3
	World total	*28*
Nutria (coypu)	Argentina	3
	North America	1.25
	Poland	1
	World total	*6*
Fox	Scandinavia	3.4
	World total	*4.1*
Karakul (Persian lamb)	Afghanistan	2
	South Africa	1
	Soviet Union	7
	World total	*11*

PTL	percutaneous – transhepatic lysis
RNA	ribonucleic acid
urso	ursodeoxycholic acid

This article is divided into three chapters that deal with substances that increase bile flow (choleretics, Chap. 1), the dissolution of gallstones in the gallbladder and bile duct (Chap. 2), and drugs used for liver therapy (Chap. 3).

1. Choleretics

Although the gallbladder is not one of the most vital organs of the human body, it causes many subjective complaints and objective changes, so that it continues to be a subject of great interest in both research and medicine. Numerous substances have been tested in animals with a view to stimulating bile flow or inhibiting lithogenesis (i.e., stone formation). Stimulation of bile flow has been attributed to several substances [1].

A *cholagogue* is a substance that increases bile flow. Cholagogues may be either *choleretics,* which stimulate secretion of bile by the liver, or *cholekinetics,* which lead to emptying of the gallbladder [2].

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a12_143

The major constituents of bile are the surface-active bile acid salts; other components include cholesterol, phospholipids, bilirubin, mucus, and inorganic salts. Bile is produced in liver cells and secreted into the bile ducts. It then passes through a shunt into the gallbladder, where it is concentrated to about one-tenth of its original volume. After ingestion of food, the gallbladder contracts and forces the concentrated bile into the duodenum via the common bile duct [3].

On the average, about 500 – 600 mL of bile is produced daily. Secretion of water and electrolytes into the bile duct system is stimulated by

1) secretin,
2) the autonomous nervous system,
3) changes in pressure in the bile duct, and
4) changes in the flow of blood through the liver.

The most important function of bile is the digestion of fats: it emulsifies ingested fats and activates pancreatic lipase.

Cholagogic drugs have not become established in English-speaking and Scandinavian countries, where they are viewed rather skeptically by the medical field. However, in other European countries where medicine is more inclined to speculation, these substances still play a surprisingly important role. Many of them have been tested only in animals, and their effects were found to be species dependent. However, results obtained in animal experiments cannot be extrapolated to humans, and investigations on humans have generally used unsatisfactory methods (e.g., duodenal probes). When reliable methods were employed to test choleretics in humans, only the bile acid preparations were found to be effective [4]. The choleresis observed on administration of bile acids involves an increased secretion of water and electrolytes (i.e., hydrocholeresis) and can also be observed during spontaneous fluctuations of bile secretion or after intake of food. True choleresis, i.e., increased secretion of bile-specific substances, cannot be induced by drugs. In addition to these drawbacks, unlimited therapeutic use of choleretics cannot be recommended for any single disease of the digestive tract [5]. Substances native to the body (bile preparations), plant drugs, and synthetic compounds are prescribed as therapeutic choleretics. However, they must be viewed in light of the above statements.

1.1. Natural Products

Bile Preparations. Substances native to the body are supplied as choleretics in the form of bile preparations and their derivatives. They stimulate the secretion of bile in the liver. The active agents in these preparations are sodium glycocholate [*475-31-0*] and sodium taurocholate [*81-24-3*]. (Glycocholic and taurocholic acids are formed by conjugation of the bile acid cholic acid with glycine or taurine, respectively.) Further choleretics are the naturally occurring bile acids (e.g., cholic and deoxycholic acids) and dehydrocholic acid, which is obtained by oxidizing cholic acid .

Cholanic acid [*25312-65-6*]

Deoxycholic acid [*83-44-3*]: 3,12-dihydrocholanic acid
Cholic acid [*81-25-4*]: 3,7,12-trihydroxycholanic acid
Dehydrocholic acid [*81-23-2*]: 3,7,12-trioxocholanic acid

Trade Names. Decholin (Casella-Riedel, Frankfurt), Agicholit (Brunnengräber, Lübeck), Chol-Arbuz (Schwag, München), Gallo Sanol (Sanol, Monheim).

Plant Drugs. Drugs obtained from plants constitute the largest number of cholagogues and are used in tea mixtures or other preparations. In addition, special products also contain bile acids, spasmolytic agents, and substances that stimulate digestion.

The most frequently used medicinal herbs are *Berberis vulgaris* (barberry), *Chelidonium majus* (celandine), different types of turmeric, *Cynara scolymus* (artichoke), *Peumus boldus* (a South American plant), *Mentha piperita* (peppermint), *Raphanus sativus* (black radish), and

Taraxacum officinale (dandelion). Very few of the drugs extracted from these plants have been investigated chemically or pharmacologically. The active ingredients of turmeric and artichoke are described in Sections 1.2.1 and 1.2.2.

Trade Names. Cholagogum capsules (Nattermann, Köln), Cholagutt-A (Albert-Roussel, Wiesbaden), Choleodoron (Weleda, Schwäbisch Gmünd), Galleb (Hover, Neuss), Heparaxal (Roland, Essen), Bilicura (Müller, Göppingen), Hepata (Madaus, Köln).

1.2. Synthetic Products

1.2.1. Benzyl Alcohol Derivatives

The choleretic ingredient of the plant drug turmeric (*Curcuma*) is *p*-tolylmethylcarbinol. Synthetic choleretics based on this structure have been developed by lengthening the aliphatic carbon chain or modifying the substituents of the aromatic ring. Reaction of the carbinol with a dicarboxylic acid gives a monoesterified acid whose sodium and diethanolamine salts are water-soluble [6]. Among the large number of compounds synthesized, the following are of practical importance.

1-Phenylpropanol [*93-54-9*], $C_9H_{12}O$, M_r136.19, *bp* (101.3 kPa) 219 °C.

1-Phenylpropanol is obtained (1) by reaction of ethylsodium with benzaldehyde in toluene and decomposition of the reaction product with water or (2) from benzaldehyde and ethylmagnesium halogenides [5]. Its toxicity is low; the oral LD_{50} in rats is 1500 mg/kg [1], [2], [6].
Trade Name. Felicur (Asche, Hamburg).

1-Phenylpentanol [*583-03-9*], fenipentol, C_{11} $H_{16}O$, M_r164.25, *bp* (1.62 kPa) 123 – 124 °C, is obtained by condensing styrene oxide with ethyl acetoacetate to form α-aceto-γ-phenyl- γ -butyrolactone. Decarboxylation and Wolff –Kishner reduction of this compound give 1-phenylpentanol [7] (see next page, on top).

The oral LD_{50} in mice is 3.10 g/kg [3], [8], [9].
Trade Name. Cholipin (Thomae, Biberach).

1.2.2. Cinnamic Acid Derivatives

Cynarin [*30964-13-7*], 1,4-bis(3,4-dihydroxycinnamoyloxy)-3,5-dihydroxycyclohexanecarboxylic acid, $C_{25}H_{24}O_{12}$, M_r516.44, *mp* 225 – 227 °C.

For structural elucidation and synthesis, see [10]. Cynarin is a cinnamic acid derivative found in artichokes. It possesses choleretic properties, lowers the cholesterol level in blood, and is a mild diuretic [11].

Toxicity is low, although use of high dosages for long periods can cause a pathological decrease in liver and kidney function [12].
Trade Name. Cynarix (Sagitta, Feldkirchen).

Dimecrotic acid [*7706-67-4*], 2,4-dimethoxy-β-methylcinnamic acid.

Dimecrotic acid is a choleretic agent with spasmolytic properties. It is obtained by reaction of resorcinol with acetoacetate to give 4-methyl-7-hydroxycoumarin. Treatment with dimethyl sulfate and sodium carbonate gives the final product [13].
Trade Name. Hepadial (Lab. Biocodex, Montrouge Cedex).

1.2.3. Miscellaneous Synthetic Choleretics

Cyclobutyrol [*512-16-3*], α-ethyl-1-hydroxycyclohexaneacetic acid, $C_{10}H_{18}O_3$, M_r186.24, *mp* 81 – 82 °C; sodium salt, *mp* 299 – 300 °C.

Cyclobutyrol is a choleretic without cholekinetic action [14]. The ethyl ester is obtained via the Reformatsky reaction by heating cyclohexanone with ethyl α-bromobutyrate in anhydrous benzene in the presence of zinc oxide. The ester is saponified to give the product [15].
Trade Name. Hebucol (Logeais, Issy-les-Moulineaux).

β-(1-Methoxy-4-naphthoyl)propionic acid [*3562-99-0*], $C_{15}H_{14}O_4$, M_r258.26, *mp* 172 – 173 °C.

This substance proved to be the most effective compound in tests carried out on ketocarboxylic acids derived from naphthalene. It is obtained by reaction of 1-methoxynaphthalene with succinic anhydride in the presence of Friedel – Crafts catalysts [16].
*Trade Names.*Magnesium salts: Icteryl, Hepalande (Delalande, Courbevoie).

***N*-(Hydroxymethyl)nicotinamide** [*3569-99-1*], $C_7H_8N_2O_2$, M_r152.15, *mp* 141 – 142 °C.

N-(Hydroxymethyl)nicotinamide is obtained by reaction of nicotinamide with formaldehyde in the presence of potassium carbonate [17]. It is a chemotherapeutic agent used against various cocci, *Escherichia coli, Proteus vulgaris,* and other pathogenic agents involved in inflammation of the biliary tract and the gallbladder. The nicotinamide moiety is responsible for its choleretic and spasmolytic action [18].
Trade Name. Bilamid (Cilag-Chemie, Alsbach-Bergstraße).

Anethole trithione [*532-11-6*], 5-(4-methoxyphenyl)-3*H*-1,2-dithiole-3-thione, $C_{10}H_8OS_3$, M_r240.36, *mp* 111 °C, is obtained as follows [19]:

Anethole trithione has choleretic and mild cholekinetic properties. It also increases the formation and excretion rates of urea and thus has a diuretic effect [20].
Trade Name. Mucinol (Plantorgan, Bad Zwischenahn).

Azintamide [*1830-32-6*], 2-[(6-chloro-3-pyridazinyl)thio]- *N,N*-diethylacetamide, $C_{10}H_{14}ClN_3OS$, M_r259.77, *mp* 97 – 98 °C, can be obtained by treatment of 3,6-dichloropyridazine with hydrogen sulfide and subsequent reaction of the 6-mercapto compound with *N,N*-diethylchloroacetamide:

Azintamide can also be obtained by reacting the acetyl chloride derivative of the mercapto compound with diethylamine [21]:

Azintamide is highly effective and is quickly absorbed from the intestine. It increases bile flow and has neither an excitatory nor an inhibitory effect on the central nervous system [22].
Trade Name. Orgallin (Hormon Chemie, München).

Hymecromone [*90-33-5*], 7-hydroxy-4-methylcoumarin, $C_{10}H_8O_3$, M_r176.16, *mp* 194 –195 °C.

Hymecromone is obtained by reaction of resorcinol with acetoacetate [23]. It is a spasmolytic agent that selectively acts on the bile ducts, particularly on Oddi's sphincter. Sphincter diastole is lengthened, and bile flow into the intestine increases. Hymecromone also possesses choleretic properties [24].
Trade Name. Cantabilin (Medica, Lipha, Lyon).

Moquizone [*19395-58-5*], 2,3-dihydro-1-(4-morpholinylacetyl)-3-phenyl-4(1 *H*)-quinazolinone, $C_{20}H_{21}N_3O_3$, M_r351.41, *mp* 135 – 137 °C; hydrochloride, *mp* 210 – 214 °C.

Moquizone is synthesized by reacting 2,3-dihydro-4(1 *H*)-quinazolinone with chloroacetyl chloride and subsequently with morpholine [25].

Moquizone exhibits choleretic effects in animal experiments [26].
Trade Name. Peristil (Recordati, Milano).

2. Dissolution of Gallstones

Chemical gallstone dissolution (litholysis) can be achieved by four methods:

1) oral therapy with the bile acids chenodeoxycholic or ursodeoxycholic acid,
2) direct percutaneous – transhepatic lysis with methyl *tert*-butyl ether,
3) oral litholysis after extracorporeal shockwave lithotripsy,
4) direct dissolution of bile duct stones via a nasobiliary tube or T-tube.

2.1. Gallstone Pathophysiology

Classification of Gallstones. Gallstones consist of a mixture of cholesterol, pigments, calcium bilirubinate, inorganic calcium salts, electrolytes, heavy metals, fatty acids, mucins and mucoproteins. The predominant component in the stone provides its name. The most common gallstone found in patients in industrialized countries is the *cholesterol stone; pigment stones* occur less frequently. Cholesterol stones contain at least 75 % cholesterol, whereas pigment stones contain no more than 25 % cholesterol [27]. An interesting pigment stone is the black pigment stone; little is known about its pathogenesis and composition. Concretions consisting predominatly of fatty acids are extremely rare. The composition, incidence, and physiological sites of occurrence of gallstones are summarized in Table 1.

Table 1. Classification, incidence, and localization of human gallstones

Type of stone	Composition	Prevalence	Localization
Cholesterol stone	$\geqq$70 % cholesterol, pigments, calcium salts, mucins, proteins	70 – 90 % of all gallbladder stones [28]	gallbladder; in 15 % of patients, gallbladder plus common bile duct
Composition stone (mixed stone)	like cholesterol stones, but with significantly lower cholesterol content (30 – 70 %)	20 %; higher in older patients	like cholesterol stones
Calcium bilirubinate stone (brown pigment stone)	$<$ 30 % cholesterol, high calcium bilirubinate content	60 % of all common bile duct stones after cholecystectomy	common bile duct; rare in the gallbladder
Black pigment stone	black pigment, mucins, proteins	5 – 30 % of all gallbladder stones [28]	gallbladder; rare in the common bile duct

Stone Formation. Formation of cholesterol stones is induced by a hepatic metabolic disorder. In the liver of gallstone carriers, the activity of β-hydroxy-β-methylglutaryl coenzyme A (HMG-CoA) reductase – the key enzyme of cholesterol synthesis – is increased. In addition, 7-α-hydroxylase, which catalyzes one of the steps in the conversion of cholesterol to bile acids, is diminished [29]. This results in high secretion of cholesterol and low secretion of bile acids into bile. Bile acids are essential for the micellar dissolution of water-insoluble cholesterol. Thus, when micellar capacity is exhausted by increased cholesterol output, cholesterol precipitates and forms cristals. A glycoprotein, probably secreted by the gallbladder mucosa, serves as a nucleation factor in initial stone formation [30]. Mucin production by the gallbladder wall and also gallbladder function play an important role in stone formation. Furthermore, stone formation depends on the sex of the patient and is affected by diet, body weight, race, and diseases of the liver and the intestinal tract [30–33].

Little is known about the formation of black pigment stones. Their incidence is higher in urban populations and in patients who consume a protein-rich diet. Hemolytic diseases associated with a surplus of unconjugated bilirubin are relevant. Brown calcium bilirubinate stones in the billiary tree form after increased bacterial deconjugation of bilirubinate – diglucuronide in bile duct infections. Therefore, these stones are found mostly after cholecystectomy or as a relapsing (recurrent) stone after endoscopic papillotomy. They often occur in rural populations with a low-protein diet.

2.2. Oral Dissolution of Gallbladder Stones with Bile Acids

Oral administration of the bile acids *chenodeoxycholic acid* [*474-25-9*] (cheno) or *ursodeoxycholic acid* [*128-13-2*] (urso) is indicated only in patients with cholesterol gallbladder stones. Chenodeoxycholic acid is given in a dosage of 15 mg per kilogram body weight daily. Dissolution rate is dose dependant and is augmented by a low-cholesterol diet [34]. Urso preparations are given in a daily dosage of 10 mg per kilogram body weight daily. Higher doses are of no avail [35].

Mode of Action of Bile Acids. Chenodeoxycholic acid acts by inhibiting HMG-CoA reductase and the 7-α-hydroxylase in the liver (cf. Section 2.1) [29]; this diminishes the secretion of cholesterol and bile acid into bile. The administered chenodeoxycholic acid is also secreted into bile, where it solubilizes the cholesterol incorporated in the stones by means of micelle formation.

Ursodeoxycholic acid has little influence, if any, on HMG-CoA reductase and the micellar dissolution of stone cholesterol. It acts by forming cholesterol liquid crystals

(phospholipid – bile salt – cholesterol vesicles) and inhibiting cholesterol reabsorption in the intestine [36], [37].

Cheno- and ursodeoxycholic acid act differently; both mechanisms are used for chemical stone dissolution. Dosage reduction of the individual bile acid is possible in combination therapy [38] and diminishes their side effects, i.e., diarrhea and elevation of transaminases with chenodeoxycholic acid, or stone calcification with ursodeoxycholic acid.

Patient Selection. Therapeutic success depends largely on patient selection. Criteria for successful treatment are

1) radiolucent cholesterol stones in the gallbladder,
2) gallbladder less than 50 % filled,
3) stone diameter $\leq$1.5 cm,
4) functioning gallbladder after stimulation,
5) patent (i.e., unobstructed) cystic duct,
6) patent common bile duct, and
7) patient compliance.

Contraindications for oral stone dissolution are as follows:

1) pigment stones and calcified stones,
2) stone diameter >1.5 cm,
3) stones in the cystic duct or common bile duct,
4) acute or chronic cholecystitis,
5) suspected bile duct carcinoma,
6) marked gallbladder septa,
7) acute or chronic liver disease,
8) chronic intestinal inflammation,
9) acute gastric or duodenal ulcer, and
10) frequent severe colics or constant pain.

Ultrasonic imaging reveals whether stones are present. A subsequent X-ray shows ring-shaped or totally calcified stones. Oral or intravenous cholecystography allows differentiation between pigment and cholesterol stones and provides information regarding stone number, age, and central spotlike calcifications.

According to [39], only 24 % of gallstone patients are suitable for conservative medical treatment; a second study reports a figure of 59 % [40]. This discrepancy is a result of the composition of the patient cohort: in the first study, only patients with advanced gallstone disease were examined; in the second study, early forms of stone disease were investigated.

Clinical Results. Complete stone dissolution is achieved with monotherapy (cheno: 15 mg kg^{-1} d^{-1}; urso: 10 mg kg^{-1} d^{-1}) in ca. 60 % of all patients treated (Table 2) [41–43]. Combination therapy (cheno + urso, half dosage each) is reported to induce dissolution more rapidly than monotherapy, according to a study in 120 patients [38]. The therapeutic result depends mostly on stone size and treatment time. Small concretions of about 0.5 cm can be dissolved in 80 – 90 % of patients, but stones with a diameter of 2 cm rarely dissolve [41], [42], [44]. The mean treatment time for stones up to 1.5-cm diameter is 19 months [45].

About 40 % of successfully treated patients experience stone recurrence [46]; these stones are usually cholesterol stones that can be dissolved within a few months. Recently it has been shown that the recurrent stone should be treated immediately after its detection and not just after colics or abdominal pain has developed. Using this treatment scheme 80 – 90 % of the patients remain stone free after 5 years.

2.3. Direct Percutaneous – Transhepatic Lysis (PTL) of Gallbladder Stones

Cholesterol gallbladder stones were first dissolved with percutaneous – transhepatic lysis (PTL) in 1985 [45]. Dissolution was performed with 2 – 10 mL of methyl *tert*-butyl ether [*1634-04-4*] (MTBE) which was instilled directly into the gallbladder and reaspirated immediately. Treatment requires 1 – 2 d and produces a few mild side effects (e.g., nausea, vomiting, and mild upper abdominal pain) [47]. Leakage of bile into the peritoneal cavity after withdrawal of the perfusion catheter presents a certain risk.

The therapeutic success of PTL is greater than 90 %, at a cost of ca. 200 DM ($ 100) per patient [48]. Further therapeutic results are summarized in Table 3. MTBE-therapy is contraindicated by the following:

1) calcified stones and pigment stones,
2) obstruction of the cystic duct,
3) acute or chronic cholecystitis,
4) small gallbladder bed area, and
5) gallbladder anomalies.

Table 2. Gallstone dissolution in patients treated with chenodeoxycholic acid (cheno), ursodeoxycholic acid (urso), or cheno vs. urso.

Bile acid ∗	Patients		Dosage	Stone		Patients with
	No.	Body weight, kg	mg kg^{-1} d^{-1}	No. (mean)	Mean size, cm^2	complete stone dissolution, %
Cheno	28	65.4	15.0	8	4.9	60.7
Urso	135	63.8	11.3	12	4.0	62.2
Cheno vs.	20	60.9	15.8 cheno	8.5	1.1	61.0
urso	28	64.5	11.5 urso	17	0.3	85.0

∗ Patients were treated with Chenofalk and Ursofalk (Falk Pharma, Freiburg, Federal Republic of Germany).

2.4. Oral Litholysis after Extracorporeal Shock-Wave Lithotripsy (ESWL)

Extracorporeal shock-wave lithotripsy (ESWL) is based on the concentration of an energy wave produced by spark discharge to a radiologically or sonographically localized gallbladder stone [49]. However, because the resulting stone fragments remain in the gallbladder, ESWL is possible only in combination with oral litholysis; therefore, patients must be selected carefully (cf. Section 2.2). After approximately six months, the combination method ESWL – litholysis completely removes solitary stones with a diameter of 2 cm in about 80 % of patients. Patients with three 1-cm stones become stone free after 18 months. Disadvantages of the treatment are its very high cost (the gallstone lythotriptor costs ca. 3.2×10^6 DM $\approx$ \$ 2×10^6), and only three concretions can be fragmented in any one patient. Furthermore, ESWL is unsuitable for calcified cholesterol and pigment stones.

Table 3. Results of stone dissolution with MTBE – data from 21 European centres

Number of patients scheduled for therapy	803
Placement of catheter successfully	761 (94.8 %)
Mean stone number and range	7.0 (1 - 68)
Mean stone size (cm) and range	1.6 (0.3-4.5)
Patients with solitary stones	197/761 (25.9 %)
Patients with multiple stones	564/761 (74.1 %)
Stone dissolution (> 90 % of stone burden)	724/803 (95.1 %)
	724/724 (90.2 %)
Residual sludge in the gallbladder after catheter removal	315/724 (43.5 %)
Bile leak after catheter removal	39/761 (5.1 %)
Patients with minor complications	129/803 (16.1 %)
Method related lethality	0/803 (0 %)
30-day lethality	3/803 (0.4 %)

2.5. Direct Dissolution of Bile Duct Stones

Bile duct stones are removed endoscopically in over 90 % of patients [50], [51]. Chemical dissolution is seldom indicated [52]. For cholesterol stones, 2 – 5 mL of glyceryl monooctanoate is infused via a T-tube or a nasobiliary tube into the bile ducts. Complete stone dissolution has been achieved in 50 – 60 % of 600 patients treated. Side effects are epigastric pain and diarrhea. Average treatment time is three weeks. Methyl *tert*-butyl ether is not suitable (or only suitable in the hands of an expert) for dissolution because it flows into the intestine where it is reabsorbed and has an anesthetizing effect (see also Table 3).

Calcium bilirubinate concrements account for up to 60 % of all bile duct stones found after cholecystectomy and can be dissolved by perfusion with an alkaline, buffered ethylenediaminetetraacetate solution (10 – 15 mL/h) [53]. In vitro, this solution dissolves almost all calcium bilirubinate stones and even black pigment stones within 30 h [54]. The aqueous solution is adjusted to pH 9.4 with sodium hydroxide and contains the following:

disodium ethylenediaminetetraacetate	1.0 %
cholic acid	0.5 %
ursodeoxycholic acid	0.5 %
carnosine	0.5 %
arginine	1.9 %

The ethylenediaminetetraacetate solution acts by chelating calcium from calcium bilirubinate to produce sodium bilirubinate which is water soluble [55]. In combination with PTL – MTBE therapy (described in Section 2.3), it can also be used for the direct treatment of pigment stones in the gallbladder.

2.6. Critical Assessment of Chemical Stone Dissolution

Any new method for treatment of gallstones must be compared with surgery (cholecystectomy) which has been practiced since 1882. Cholecystectomy has an age-dependent lethality of 0.1 – 4 % (mean 0.4 %) and is a well-established, low-risk method. However, despite modern presurgery diagnostics, 25 – 40 % of patients who have undergone surgery suffer from the postcholecystectomy syndrome (i.e., from the same complaints as before surgery) [56], [57]; in ca. 10 – 15 % of all patients, recurrent stones develop in the bile ducts [50].

The advantages of oral stone dissolution with cheno- or ursodeoxycholic acid are the easy administration of the preparation and the absence of fatalities. A disadvantage is the high rate of stone recurrence (ca. 40 %). The cost is identical to that of surgical therapy.

A final assessment of PTL – MTBE treatment is still premature. Extracorporeal shock-wave lithotripsy with subsequent oral litholysis may be useful in the treatment of stones with diameters >1.5 cm.

A logical therapeutic concept for treating gallstones is as follows:

1) Silent gallbladder stones should not be treated but should be monitored.
2) Cholesterol stones in a functioning gallbladder, which have a diameter of 1.5 – 2.0 cm and produce mild symptoms, are suitable for oral litholysis.
3) Cholesterol stones with a diameter of 1.5 – 2.0 cm in a functioning gallbladder are suitable for the combination for ESWL therapy and oral dissolution with bile salt.
4) Cholesterol stones in a functioning gallbladder, which measure up to 3 – 4 cm or fill the gallbladder to more than 50 % and produce marked symptoms, are suitable for PTL – MTBE therapy.
5) Surgery is indicated in patients with frequent colics and all complications (e.g., cholecystitis, shrunken gallbladder, empyema, obstructed cystic duct, calcified stones, and pigment stones).
6) Since laparoscopic cholecystectomy has been introduced in 1985, oral litholysis, ESWL therapy and contact litholysis with MTBE are less important in the treatment of gallstone disease. The advantages of laparoscopic operations are: a lower lethality rate, a shorter hospital stay, rapid reconvalescence. The disadvantages are: a higher morbidity rate and higher costs.

3. Liver Therapeutics

3.1. Introduction

Drug therapy for liver disease is unsatisfactory from many points of view. Because the liver occupies a key position in metabolism, it has an enormous amount of reserve energy that is used to only a small extent under normal circumstances. It receives a more than adequate supply of the building blocks required for its varied, rapid metabolic reactions via the portal vein and the hepatic artery. Like all other parenchymatous organs, the liver requires stimulation of its functions to maintain its normal structure [58].

Partial, temporary, or permanent collapse of liver function caused by serious injury to the organ cannot be overcome by drug administration. Similarly, irreversible structural changes cannot be reversed by pharmacotherapy [59].

Prophylactic therapy can be used to prevent liver damage. Additional, medicinal protection is possible to only a limited extent and is normally unnecessary because of the liver's enormous reserve energy supply and regenerative capacity. This might appear improbable in view of the range of preparations available on the European market for the "protection" of the liver. However, critical analysis of these preparations shows that they are:

1) experimental products used without any scientific basis,
2) substances uncritically recommended for use in humans on the basis of animal experiments, or
3) products chosen on the basis of speculation and inadequate knowledge of intermediary metabolism.

Liver disease is caused by many different pathogenic agents; consequently, no single drug can be effective against all types of disease. The task of the clinician is to find out which

therapeutic measures can be employed to restore liver functions that have failed partially or totally. Potentially successful therapeutic substances should possess the following pharmacological properties:

1) Stimulation of the lowered cell metabolism
2) Stimulation of the reticuloendothelial system, particularly in the hepatic region, thereby causing an increase in the phagocytic capacity of the reticuloendothelial Kupffer cells
3) Maintenance or recovery of the intra- and extracellular structure of the membrane and its functions
4) A positive regenerative effect
5) An anti-inflammatory effect
6) Antitoxic properties
7) Good absorption from the digestive tract
8) Preferential excretion in the enterohepatic circulation
9) Lack of properties that are toxic or impose a stress on liver cells
10) Enhancement of detoxification by effective entrapment of radicals
11) Absence of side effects

The vitamins, amino acid cocktails, and other preparations available for protection of the liver should be considered obsolete. Only a few substances are important for the treatment of liver disease; these include the corticosteroids, immunosuppressive agents, and silymarin [60], [61].

Almost all the therapeutic measures discussed below had their origins in the United States, where they have long since been forgotten. However, they seem to have an undeserved ability to survive in continental Europe [59], [62], [63].

The classical experiments of Opie and Alford proved that animals fed a carbohydraterich diet could withstand chloroform-induced narcosis better than those receiving a low-carbohydrate diet. Liver glycogen has since been considered to be one of the factors responsible for the protection of liver cells. Subsequent animal experiments demonstrated that chloroform sensitivity was associated with protein, rather than sugar, metabolism; thus proteins became of interest. In rats, deficiency or lack of the lipid-mobilizing (lipotropic) substances choline and methionine caused fatty liver and led to cirrhosis, whereas a diet lacking cystine (or cysteine), methionine, and vitamin E resulted in liver necrosis [60], [64], [65]. These animal experiments, however, were carried out under extreme conditions that are unlikely to occur in humans. Choline, cysteine, and methionine were used either singly or in combination in most of the so-called preparations for "protection" of the liver. As expected, they never produced convincing results [66–68].

Different vitamins, particularly those belonging to the B group, form the "hard core" of liver protection therapy. Of these, vitamin B_{12} is the most important. Although the ineffectiveness of vitamin B_{12} therapy in acute hepatitis, chronic hepatitis, and liver cirrhosis has been proved biochemically and clinically [60], it is still remarkably popular. The effectiveness of various vitamin combination drugs has not yet been proved by controlled chemical trials.

3.2. Therapeutic Agents

Liver diseases are heterogeneous and differ in their etiology. This fact must be taken into consideration in their treatment. After careful diagnosis, a suitable substance must be selected to achieve a therapeutic effect.

3.2.1. Inhibitors of Viral Nucleic Acid Synthesis

Acyclovir [*59277-89-3*], 9-(2-hydroxyethoxymethyl)guanine, is a nucleoside with very low toxicity and strong virostatic properties (→ Chemotherapeutics).

In herpes virus infections, acyclovir must first be activated to acyclovir monophosphate by the viral thymidine kinase and then converted to acyclovir triphospate by cellular phosphotransferases. Acyclovir triphosphate inhibits viral DNA polymerases by competitively displacing deoxyguanosine. Although the hepatitis B virus (HBV) does not possess any endogenous thymidine kinase, a transient decrease in HBV-specific

DNA polymerase has been described in some cases [69]. Intravenous administration was accompanied by some serious side effects, while very low concentrations in blood plasma could be detected after oral administration of the drug. Proacyclovir (6-desoxyacyclovir) BW515 is absorbed very well from the intestine. Results indicate that acyclovir and proacyclovir could become valuable adjuvant drugs in a virostatic combination therapy for chronic hepatitis B [70–73] .
*Trade Name.*Zovirax (Wellcome, Burgwedel)

Intercalary Substances. Some substances that can inhibit DNA polymerase in vitro (quinacrine, chloroquine, chlorpromazine, and primaquine) have also been tested in clinical studies on patients with chronic hepatitis B. Therapeutic efficiency has not yet been proved [72], [74], [75].

Interferon. Interferon comprises a set of biological proteins with antiviral and immunomodulatory activity (→ Interferons). Interferons can alter the course of viral infection by inhibiting intracellular virus replication and by modifying the immune responses to viral antigens in body fluids and on cellular surfaces [76–78]. The α- and β-interferons are induced by viral replicative events in all types of cells and are thus probably important during the early phases of an infection [58]. γ-Interferon is produced as a result of the formation of antigen-sensitized T cells and probably exerts its effect during later stages or during chronic infection [77], [79], [80].

Phosphonoformic Acid [*4428-95-9*].
Sodium phosphonoformate [*63585-09-1*] is a pyrophosphate analogue that selectively inhibits viral nucleic acid synthesis (→ Chemotherapeutics). The formation of triphosphate nucleotides by polymerases, which is essential for the synthesis of RNA and DNA, is prevented by this substance [78]. The HBV DNA polymerase is also inhibited by phosphonoformic acid in vitro and in experiments on chimpanzees. However, the substance does not appear to be suitable in the treatment of humans, because the phosphate moiety may accumulate in the bones and delayed toxic effects cannot be ruled out. Moreover, it must be administered intravenously at relatively short intervals, which makes long-term treatment difficult [72], [74], [77].

Ribavirin [*36791-04-5*], 1-β-D-ribofuranosyl-1*H*-1,2,4-triazole-3-carboxamide, is a nucleoside analogue that acts against a broad spectrum of RNA and DNA viruses in vitro by inhibiting the biosynthesis of guanosine monophosphate. It accumulates in the liver but does not appear to affect the reproduction of HBV. Therapeutic tests show that the substance does not favorably influence the course of chronic hepatitis B [80], [81].

Vidarabine [*24356-66-9*], 9-β- D-arabinofuranosyl-adenine (ara-A) and its monophosphate (ara-AMP) [*29984-33-6*] are purine nucleosides with strong virostatic properties (→ Chemotherapeutics). They selectively inhibit the activity of viral DNA polymerase and thereby prevent synthesis of the complementary minus-strand DNA from the viral pregenome [82], [83].

Vidarabine

The decrease in DNA polymerase activity specific to hepatitis B virus is faster and greater after treatment with ara-A or ara-AMP than with interferon. However, when treatment is discontinued, DNA polymerase activity usually reaches the initial values observed before treatment. Continued inhibition of HBV replication after discontinuation of therapy occurs about as often as after treatment with interferon [84]. In comparison with the monophosphate ester ara-AMP, ara-A has the disadvantage of requiring large infusion volumes in clinical therapy. Generally, therefore, the more water-soluble derivative ara-AMP is used. The monophosphate ara-AMP can also be administered intramuscularly and is suitable for treatment of outpatients. However, daily dosages of 5 – 10 mg per kilogram of body weight for a period of 28 days are only

slightly effective. Longer treatment periods or higher doses lead to serious, extremely painful and long-lasting polyneuropathies that disappear very slowly after discontinuation of treatment. This neuromuscular pain syndrome begins mainly in the lower extremities in the form of a "burning feet syndrome." Other side effects include tiredness, listlessness, loss of appetite (occasionally with mild nausea), and slight depletion of bone marrow which is reversible after discontinuation of the drug [73], [82].
Trade Name. Vidarabin (Dr. Thilo, Sauerlach)

3.2.2. Bile Salts used for Primary Biliary Liver Disease

Ursodeoxycholic acid is a naturally occurring bile salt in humans. It is rapidly absorbed in the small intestine and excreted with the bile. Ursodeoxycholic acid is the drug of choise for the treatment of primary biliary cirrhosis and primary sclerosis cholanyitis. The daily dose amounts to 10 – 15 mg/kg. It has no side effects even after a treatment period of up to 20 years.

In primary biliary cirrhosis, it improves the laboratory data significantly by 50 – 80 % and the symptoms in 30 – 40 % of the patients. Ursodeoxycholic acid prevents or delays the development of oesophageal varices and prolongs life expectancy. Better results are obtained when ursodeoxycholic acid is combined with the glucocorticoid budesonide.

3.2.3. Natural Substances

Cyanidanol [*154-23-4*], Catergen, (+)-catechin, (+) 3-cyanidanol, (2*R*,3*S*)-3,3′,4′,5,7-pentahydroxyflavan, was isolated in 1830 from a series of plants of African, American and Indian origin (*Uncaria gambir*). Unequivocal elucidation of its stereochemical structure was carried out in the late 1950s [85].

Cyanidanol is absorbed rapidly from the gastrointestinal tract. Its concentration in blood reaches a maximum after 1 – 2 h. Excretion takes place mainly as the glucuronide and sulfate conjugates in the urine [86–88].

Unchanged cyanidanol is present in only small amounts in the liver because almost all of it is metabolized rapidly during its first passage through the organ. Eleven metabolites have been isolated [89–92].

Investigations with radioactively labeled cyanidanol have shown that about 27 % of the administered dosage is excreted in the urine after 3 h and between 70 and 88 % after 27 h. This catechol lacks liver specificity because of its rapid urinary elimination. Furthermore, the substance is inactivated where it is supposed to act, i.e., in the liver. Because of its serious, sometimes fatal side effects, this compound was withdrawn from the market in 1987 [92–94].

Silymarin is obtained from the milk thistle – *Silybum marianum* (L.) Gaertn. or *Carduus marianus* (L.) – a medicinal plant known since ancient times. For structural elucidation and total synthesis of the constituents of silymarin, see [94], [95]. Silymarin is a general term used to describe three substances derived from the milk thistle fruit: silybin [*22888-70-6*], silydianin [*29782-68-1*], and silychristin [*33889-69-9*]. For structural elucidation of these compounds, see [96], [97].

Silybin

Silydianin

Silychristin

The effects of silymarin and its main constituent, silybin, were investigated on different models of liver damage in acute, subchronic, and chronic experiments on animals. Treatment was either prophylactic or curative [98–100].

Silymarin is active against a large number of hepatotoxic substances. It exerts a positive influence on several basic cellular functions, namely, membrane integrity, of ribosomal RNA and thus of proteins, and the regenerative capacity of the liver [101], [102]. Most of these functions are influenced only in the damaged liver and not in a healthy liver [103–105].

Preparations like silymarin have a protective and stabilizing effect on the liver cell membrane due to their radical scavenger function and the resultant preventation of lipid peroxidation. Furthermore, silymarin has an immunomodulatory effect (normalization of the reduced lymphoblastic transformation activity of cirrhotic patients). Both the immunomodulatory and antioxidant activities of silymarin (Legalon) play an important role in the mode of action of this hepatoprotective preparation [64], [65], [101], [106–108].

Pharmacokinetics. About 90 % of silymarin is excreted in the bile; renal elimination accounts for ca. 10 %. The compound is conjugated in the form of glucuronides, sulfates, and sulfaglucuronides in the liver. These conjugates are then cleaved by the intestinal flora, and the active ingredient is reabsorbed. About 40 % of the absorbed substance enters this cycle, i.e., the enterohepatic circulation. Silymarin does not induce enzyme synthesis; interaction with other drugs has not been observed [64], [65], [109], [110].

Use in Alcohol-Induced Liver Disease. The therapeutic action of silymarin in diseases of the liver caused by alcohol has been well established [111–113].

The efficacy of Legalon was investigated in a double-blind study of alcohol-induced liver damage. The serum (GPT) glutamic – pyruvic transaminase and glutamic – oxalacetic transaminase (GOT) values, bromsulphalein (BSP) retention, and histological changes normalized more rapidly and more frequently in patients receiving the drug than in the control group [114].

The efficacy of silymarin was shown in patients with alcohol-induced liver disease in a randomized double-blind study. The serological parameters bilirubin, GOT, GPT, glutamate dehydrogenase (GLDH), γ-glutamyltransferase (γ-GT) and alkaline phosphatase were chosen for monitoring. Other serological and sonographic findings were used as general clinical controls. The results, particularly changes in γ-GT, GPT, GOT showed that Legalon produced significant improvement [113], [115].

Use in Occupational Liver Disease. Silymarin treatment of patients suffering from occupational liver disease led to considerable improvement of parameters that showed elevated pathological values: alkaline phosphatase, bilirubin, GOT, GPT, γ-GT, and cholinesterase [116–118].

The action of Legalon on liver function after cholecystectomy was investigated in a double-blind study. The values for GPT and γ-GT showed a statistically significant difference in favor of Legalon [61], [63].

The above results confirm other investigations on the postoperative behavior of cholinesterase and various hepatic enzymes in the presence of Legalon [112], [119].

Silymarin produced an antihepatotoxic effect, as well as a decrease in lipoprotein and triglyceride concentrations, in patients with liver damage resulting from industrial toxicity caused by silicon dioxide, lead, trinitrotoluene, and trichloroethylene. In workers from the chemical industry who were exposed continuously to xylene and/or toluene, Legalon had a signifcant protective effect on the liver [59], [60], [64].

Use in Liver Cirrhosis. In a randomized double-blind study, 170 patients with cirrhosis of the liver were treated with silymarin: 87 patients received 140 mg Legalon three times daily, 83 patients received a placebo. The average observation time was 41 months for the placebo group and 50 months for the group receiving Legalon. The survival rate was 76 ± 6 % (standard error) in patients treated with silymarin and 53 ± 8 % in the placebo group. Analysis of the subgroups indicated that treatment was effective in alcoholic cirrhosis as well as in cases classified as a cholangic biliary cirrhosis (an ailment affecting children up to 12 years of age). These results show that mortality in cirrhosis patients is lowered by treatment with silymarin [120].

In a multicenter study of *Amanita phalloides* intoxication in the Federal Republic of Germany,

Switzerland, Austria, and France, a survival rate of 91.6 % was observed in 220 patients treated with silybinin. Silybinin infusions in combination with conventional treatment represent an effective therapeutic supplement in patients with *Amanita phalloides* intoxication [106], [121–123].

Trade Names. Legalon 70, Legalon 140, Legalon Sil Ampullen, Legalon Liguidum (Dr. Madaus, Köln).

3.2.4. Miscellaneous Substances

"Essential" Phospholipids. Lecithin has been used in therapy as a hepatotropic substance ever since the liver was shown to incorporate choline into lecithin. "Essential" phospholipids (EPL) are derived from a special fraction of lecithin and isolated by chromatographic methods from a crude mixture of phospholipids obtained from soybean. They consist of naturally occurring phosphatidylcholine with an especially high content of polyunsaturated, essential fatty acids, particularly linoleic acid [124–128].

More than 50 % of EPL consists of phosphatidylcholine in which the substituents R^1 and R^2 are derived from linoleic acid:

$$CH_3(CH_2)_4CH{=}CHCH_2CH{=}CH(CH_2)_7COOH$$

The essential phospholipids differ from the phospholipids present in the body in that R^1 is derived from a polyunsaturated fatty acid (mainly linoleic acid) and not a saturated one [129], [130].

Production. Commercially available crude phosphatides of plant origin are dissolved in ethyl acetate, a lower dichlorohydrocarbon, or a mixture of the two; up to 6 vol % of alcohol may also be present. Stirring with a quantity of aluminum oxide corresponding to at least five times the crude mass of phosphatides and subsequent elution of the adsorbent with alcohol give a product that contains >90 % phosphatidylcholine. Pure phosphatidylcholine can be obtained by using propylene dichloride for desorption of the aluminum oxide, instead of alcohol. After evaporation of the solvent in an inert atmosphere under reduced pressure, phosphatidylcholine is obtained in yields of up to 88 % as an almost colorless, pasty mass.

Mode of Action. Phospholipids are constituents of biological membranes and, therefore, play an important role in membrane-dependent metabolic processes. On the one hand, the properties of therapeutically employed phospholipids containing polyunsaturated fatty acids should correspond to those native to the body. However, the cis double bonds in the polyunsaturated fatty acids prevent parallel alignment of the hydrocarbon chains of the membrane phospholipids. This should lead to a loosening of the tightly packed, micellar phospholipids and thus to a higher transmembrane exchange rate [129–131].

Therapeutic effects. Lipemia caused by ethanol is antagonized by EPL in acute as well as chronic animal experiments. Serum alkaline phosphatase and plasma protein fractions of the plasma tend to return to normal values. Cirrhosis caused by chronic administration of small doses of carbon tetrachloride is largely prevented by the simultaneous administration of EPL. However, these are less effective in treating poisoning due to galactosamine, carbon disulfide, and allyl isothiocyanate [132], [133].

In rats, orally administered EPL were absorbed completely within 24 h and reached the liver almost exclusively via the lymphatic system [134].

The liver absorbs between 10 and 15 % of the administered EPL. Excretion occurs slowly via urine and bile.

Acute viral hepatitis is considered to be amenable to EPL therapy. Administration of EPL shortens the duration of hepatitis A and B. Chronic hepatitis, chronic-aggressive hepatitis, and liver cirrhosis show clear signs of improvement following treatment with EPL [135–137].

Based on the clinical picture and laboratory results obtained after EPL therapy, this substance appears to increase the biochemical efficiency of residual parenchyma tissues. Iatrogenic injuries to the liver, caused by treatment of tuberculosis with isoniazid and rifampicin, can also be alleviated. Treatment with EPL significantly reduces fatty degeneration of liver cells

and alleviates cell membrane injury occurring during the protein-deficiency disease kwashiorkor [138], [139].

The effectiveness of EPL has been proved pharmacologically, and they are also well tolerated clinically. Thus, EPL may be regarded as a liver curative that intervenes in the form of a "substitution therapy" in hepatocyte anabolism and liver disease in which an activation of anabolic processes appears desirable [140–142].
Trade Name. Essentiale (Nattermann, Köln).

Orotic acid [*65-86-1*], 1,3,5-trihydro-2,6-dioxopyrimidine-4-carboxylic acid, uracil-6-carboxylic acid, whey acid, $C_5H_4N_2O_4$, M_r 156.10, *mp* 345 – 346 °C [143–145].

Production. The oldest known method for synthesizing orotic acid is the condensation of urea with diethyl oxalacetate and subsequent alkaline hydrolysis of the reaction product. Free orotic acid is obtained from the alkali salt by treatment with mineral acid [124–126].

A newer synthesis starts by condensing chloroacetoacetyl chlorine, obtained from diketene and chlorine, with urea to give 6-chloromethyluracil. Oxidation of the latter with hydrogen peroxide in an alkaline medium yields orotic acid [134], [146].

In another method, hydantoin or hydantonitrile is treated with glycolic acid in an alkaline medium to give carboxymethylene hydantoin, which rearranges to form orotic acid [145], [147].

Orotic acid is also produced in fermentation by using microorganisms such as *Corynebacterium, Brevibacterium, Arthrobacter,* and *Candida* [148], [149].

Mode of Action. In the liver, orotic acid is the precursor of the pyridine nucleotides of nucleic acid (→ Nucleic Acids). As a parenchymatous, glandular organ, the liver is rich in cell nuclei, where the nucleic acids are localized. Cow's milk also contains a relatively high concentration of orotic acid (6 – 10 mg/L).

Orotic acid is synthesized in the liver from aspartic acid and carbamyl phosphate in two steps. It is the precursor of the simplest pyrimidine nucleotide, uridine monophosphate, and of deoxythymidine monophosphate. The corresponding triphosphates are building blocks for ribonucleic and deoxyribonucleic acids (RNA and DNA, respectively; → Nucleic Acids) [127–131].

Uridine triphosphate is a coenzyme for the transfer of uronic acids. Uridine diphosphate glucuronic acid, and thus orotic acid, play a vital role as glucuronate donor in detoxification and elimination of substances such as steroids, drugs, and bilirubin. Although orotic acid is an essential compound for many microorganisms, it does not have any vitamin-like character in mammals [129], [130], [132], [133].
Trade Name. Hepatofalk (Dr. Falk GmbH, Freiburg).

Thioctic acid [*62-46-4*], 5-(1,2-dithiolan-3-yl)valeric acid, α-lipoic acid, $C_8H_{14}O_2S_2$, M_r 208.31, *mp* 47.5 – 48 °C, forms yellowish flakes and is sparingly soluble in water, but soluble in methanol, ethanol, diethyl ether, and chlorofom.

Thioctic acid is widespread in the plant and animal kingdom. It can be prepared by reacting 6,8-dichlorooctanoic acid with sodium disulfide (Na_2S_2) (for this and other methods of synthesis, see [150–152]).

Production. Industrial synthesis of thioctic acid is performed in three stages. Monomethyl or monoethyl adipate is converted into the corresponding acid chloride by reaction with thionyl chloride. Treatment with ethylene in the presence of anhydrous aluminum chloride yields 8-chloro-6-ketooctanoate. In the second stage, this ester is reduced to 8-chloro-6-hydroxyoctanoate by using thionyl chloride in pyridine. In the third stage, the chlorine atoms are replaced by sulfur atoms by treatment with sodium disulfide. Hydrolysis of the resulting dithionooctyl ester formed with alcoholic potassium hydroxide gives thioctic acid [153], [154].

Mode of Action and Pharmacology. The concentration of thioctic acid is highest in the liver. Its main biochemical role is as a coen-

zyme in the oxidative decarboxylation of α-keto acids. It is a constituent of acid reductase transacetylase, liponamide oxidoreductase, and the α-ketoglutarate dehydrogenase complex. Detoxifying properties can be expected from the five-membered disulfide ring, particularly that function as enzyme inhibitors [152], [155–157].

Thioctic acid is a growth factor for only certain protozoa and bacteria. However, in vertebrates it is formed by biosynthesis and thus a deficiency does not occur in humans. Nevertheless, it has been recommended in the treatment of hepatic coma, chronic hepatitis, and cirrhosis. Expectedly, no reproducible clinical success has been achieved. The antitoxic properties of thioctic acid have been utilized with partial success, for example, in treatment of poisoning caused by the deadly amanita (death cap) mushroom [158].

In humans, thioctic acid is excreted mainly in the urine within 24 h of a single oral or parenteral dose. In rats, the mucous membrane of the isolated duodenum rapidly absorbs thioctic acid within 45 min [159–162].

Trade Name. Thioctacid (Chemiewerk Homburg, Frankfurt)

3.2.5. Antifibrinogenic Drugs

Antifibrinogenic drugs inhibit the formation of fibrin.

Colchicine [*64-86-8*], isolated from the meadow saffron (*Colchicum autumnale* ; for structure and production, see → Alkaloids, Chap. 9.23.), was the first natural substance recognized for its antimitotic effect. This water-soluble alkaloid is quickly absorbed from the intestine and binds strongly to plasma proteins and cell proteins ; it is deacetylated in the liver. Colchicine accumulates in the body due to its slow breakdown, entrance into the enterohepatic circulation, and high protein binding. Colchicine inhibits microtubular protein assembly in fibroblasts, and thereby collagen formation. Toxic dosage produces acute renal damage and ascending paralysis, as well as chronic agranulocytosis, hair loss, and myopathy [163–165].

Over 4 years, 23 patients with liver cirrhosis received colchicine (1 mg/day, 5 days/week) and 20 a placebo [166]. Mortality decreased from 40 % with placebo to 17 % in the treatment group, but this decrease was not statistically significant. Ascites, encephalopathy, and splenomegaly improved significantly in the group receiving colchicine. Although the results of this study are encouraging, confirmation in a larger population sample is needed [166–171].

d-Penicillamine [*52-67-5*], $C_5H_{11}NO_2S$, M_r149.21, *mp* 198.5 °C, is a dimethyl derivative of the amino acid cysteine, which contains a sulfhydryl group (for production, see → Amino Acids).

The biochemical and pharmacological effects of D-Penicillamine can be explained by three important reactions:

1) Chelation of heavy metals
2) Exchange reaction with disulfides
3) Reaction with aldehydes

Treatment of chronic – aggressive hepatitis with D-Penicillamine is based on the following mechanism of action [172], [173]:

D-Penicillamine reacts with the aldehyde groups of the collagen precursor tropocollagen to form thiazolidines. This prevents cross-linking of tropocollagen and thus the synthesis of insoluble collagen. Inhibition of collagen synthesis has been shown in animal experiments where D-penicillamine disturbs wound healing, decreases the tensile strength of the skin, and increases dilatory capacity of the lungs due to lowered elastic resistance [173], [174].

The importance of these effects is evident in diseases in which the major pathological symptom is an excessive proliferation of mesenchyma. The inhibitory influence of D-penicillamine on the inflammatory mesenchymal reaction (i.e., on cell proliferation) can be seen clearly in liver punctates [175–177].

D-Penicillamine does not dissolve or "soften" cirrhotic cicatrizations (scars). However if treatment is started at an early stage, the histologically active process may be retarded to allow healing of the residual fibrosis. This possibility assumes particular significance when other

methods of treatment are unsuccessful [178–180].
Trade Name. Metalcaptase (Knoll, Ludwigshafen; Heyl, Berlin)

Insulin and Glucagon. In animal experiments, the presence of hepatotrophic factors in portal blood has repeatedly been documented [58]. Insulin and glucagon were shown to be particularly potent stimuli of hepatocellular regeneration [181]. Administration of these hormones ameliorated fulminant murine hepatitis [182]. Stimulation of regeneration by infusion of these hormones may be a useful approach for treatment of severe alcoholic hepatitis in humans.

A randomized, double-blind controlled trial of insulin and glucagon infusion has been conducted on patients with alcoholic hepatitis [183]. Twenty five patients received 24 units of insulin and 2.4 mg glucagon over 12 h daily for 3 weeks; another 25 patients received dextrose solution as placebo. Mortality in the treatment and placebo group was not significantly different. However, in a subgroup of 34 patients with prolonged prothrombin times, fewer deaths were observed in the treatment group. In addition, total serum bilirubin and prothrombin time improved more rapidly in the insulin- and glucagon-infused group. Complications included hypoglycemia, superficial thrombophlebitis at the site of infusion, and generalized macular skin eruptions. This type of therapy, although still experimental, seems to be a promising approach for the seriously ill patients, in whom the rate of hepatocellular regeneration might be critical for survival [184].

1. Introduction

Gallium [*7440-55-3*] is an element of group 13. Its existence was predicted by Mendeleev, and it was discoveredby Lecoq de Boisbaudran in 1875. The metal was mainly of academic interest until 1970, when it was found that compounds of gallium with group 15 elements have semiconducting properties (→ Semiconductors), and so began the extensive industrial use of the element. Gallium compounds are of particular value in optoelectronics, especially for light-emitting diodes.

2. Physical Properties

Gallium is a silvery-white metal, *mp* 29.78 °C, *bp* 2403 °C. The naturally occurring element contains two stable isotopes: ^{69}Ga (60.4 %) and ^{71}Ga (39.6 %). The density of the liquid is 6.095 g/cm^3 at 29.8 °C, and the density of the solid is 5.904 g/cm^3 at 24.6 °C. There is a volume expansion of 3.2 % on solidification.

Gallium forms orthorhombic crystals with the lattice constants $a = 0.4523$ nm, $b = 0.45198$ nm, and $c = 0.76602$ nm, and the physical properties are consequently strongly anisotropic. The thermal expansion coefficients are 1.65×10^{-5} K^{-1} along the a axis, 1.13×10^{-5} K^{-1} along b, and 3.1×10^{-5} K^{-1} along c. The electrical properties are equally anisotropic, but it is not possible to quote reliable figures owing to the great influence of purity and temperature on the electrical conductivity.

3. Chemical Properties [1–4]

Metallic gallium dissolves only slowly in dilute mineral acids, but rapidly in aqua regia and concentrated aqueous sodium hydroxide. It also dissolves slowly in solutions of hydrogen halides in ether.

In its compounds, the valency of gallium is usually 3. The monovalent state is unstable, although the monovalent gallium compounds Ga_2O and GaCl can be isolated. An oxidation state of +1 has not yet been detected in aqueous solution, but some reactions of gallium indicate that it exists.

The oxygen compounds of gallium resemble those of aluminum in that there are high and low temperature forms of Ga_2O_3 and two hydroxides, $Ga(OH)_3$ and $GaO \cdot OH$. Gallium halides have covalent character and therefore have good solubility in many nonpolar solvents in which they exist in dimeric form.

With elements of group 15, gallium forms binary compounds, of which GaP [*12063-98-8*] and GaAs [*1303-00-7*] areof great industrial importance. They may be prepared by direct combinationof the elements at high temperature.

In aqueous solution, gallium forms octahedrally coordinated aquo ions $[Ga(H_2O)_6]^{3+}$.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a12_163

There are many salts of oxoacids, such as the sulfate, nitrate, and perchlorate, and also hydrated halides.

In aqueous solution, the hexaaquo complex has an acid reaction owing to hydrolysis. Gallium salts of weak acids cannot exist in the presence of water for the same reason. Of the numerous anionic and cationic complexes, the most industrially important are the halide complexes, the $[GaX_4]^-$ ions, whose oxonium salts have good solubility in several organic solvents. This property is utilized in the extraction and purification of the metal. Other gallium complexes of industrial importance are the octahedrally coordinated chelates with β-diketones and 8-hydroxyquinolines, these also being soluble in organic solvents. Alcoholates and organic derivatives may be prepared similarly to the analogous aluminum compounds.

Gallium forms a series of alloys with other metals, sometimes even at low temperatures. Some of these, containing up to 3 % gallium, are useful in dentistry.

4. Occurrence and Raw Materials

With its natural abundance of 16 ppm, gallium is one of the rarer elements in the earth's crust. Gallium-containing minerals, the best known of which is a variety of germanite, do not have economic significance. Of the known locations, only the Apex mine in Utah has been commercially mined.

The greatest part of the world production of gallium is as a byproduct of the production of aluminum oxide. The gallium concentration in bauxite ranges between 0.003 and 0.008 %, depending on the location. The high contents occur in tropical bauxites such as Surinam bauxite, which contains 0.008 % Ga, the highest average content known. The world supply of recoverable gallium in bauxite is estimated at 1.6×10^6 t based on bauxite reserves and their gallium contents [5].

Because of the low concentration of gallium in bauxite, it is not economic to mine bauxite to extract gallium. The amount of gallium available from bauxite is then determined by the amount of aluminum oxide that is produced. For the year 1986, complete utilization of the gallium from aluminum oxide production would have corresponded to a theoretical production of ca. 2000 t of gallium. The gallium contained in zinc ore (sphalerite) has lost economic importance due to the changeover to hydrometallurgical methods of zinc extraction. The reserves of gallium in zinc ores worldwide has been estimated to be 6500 t [5].

The largest reserves of gallium are contained in phosphate ores and in coal of various kinds. When phosphorus is produced electrothermally from phosphate, the gallium is concentrated in the flue dust and may be recovered from it. Likewise, gallium may be obtained from the fly ash of coal, another material in which gallium is concentrated. Neither source is exploited at present because the gallium concentration is only 0.01 – 0.1 wt %. It is not economic to treat these materials merely to extract the gallium. The total gallium reserves in phosphates and coals have been estimated at several million tonnes. They thus considerably exceed those in bauxite [5].

5. Production

The most important process for gallium production is the extraction of the metal from the circulating liquors in the Bayer process for aluminum oxide manufacture (→ Aluminum Oxide, Chap. 3.). These contain 70 – 150 mg/L of gallium, depending on the bauxite and on the concentration of the caustic liquor. The gallium content of the liquor is also determined by the dissolution process used. Bauxite which is high in boehmite ($AlO \cdot OH$) requires high temperatures for the dissolution process, leading to more complete release of the gallium and higher concentrations in the circulating liquors.

The gallium extraction plant is usually located within or very near to the aluminum oxide works. Part of the liquor stream is diverted for gallium extraction and then recycled. In some instances the liquor undergoes a preliminary purification process to remove certain heavy metals.

Three types of process are used to extract the gallium from the circulating liquor: (1) fractional precipitation, (2) electrolytic processes, and (3) extraction with chelating agents.

Fractional Precipitation. The basis of this process is that when the gallium-containing sodium aluminate solution is treated with carbon dioxide the first product precipitated is pure

aluminum hydroxide. This increases the gallium content of the liquor. Further treatment then causes the gallium to separate along with more aluminum hydroxide. After this, fractional precipitation gives an aluminum hydroxide richer in gallium, and this is followed by one or more further fractional precipitations. The gallium-enriched aluminum hydroxide is dissolved in aqueous sodium hydroxide to give a solution of sodium aluminate and sodium gallate, from which gallium is obtained by electrolysis.

The precipitation process is used only to a small extent because of the expense of removing the byproduct sodium carbonate unless thermal decomposition is used in the aluminum oxide works. Also, on account of the many precipitation stages involved, the process is labor intensive and can therefore be used only when energy and labor costs are low. The People's Republic of China produces gallium at a rate of 5 t/a by this process.

Electrolytic Processes. The electrolytic process depends on the fact that mercury forms an amalgam with gallium from which the gallium may be extracted with a caustic soda solution. The gallium amalgam can be produced either directly (Alusuisse process) or indirectly (VAW/INGAL process).

In the Alusuisse process, the gallium is deposited directly onto the mercury cathode, using the appropriate conditions of temperature, agitation, and current density, and an amalgam is formed. In the VAW process, sodium amalgam is used to reduce the gallium present in the Bayer liquor. This gives an amalgam from which the gallium is removed by treatment with caustic alkali, and the mercury is then used again to produce sodium amalgam, i.e., the mercury circulates in a closed system.

Reduction processes have in recent years become less attractive because they require special conditions to be commercially viable. In particular, the aluminate solutions must contain over 150 g/L sodium and be very low in vanadium, tungsten, molybdenum, and iron so that the electrolytic current efficiency reaches economically acceptable values. However, such highly concentrated liquors are not produced in modern aluminum oxide plants, and therefore the electrolytic process can no longer be used in new installations. The environmental problems associated with mercury further discourage the use of electrolytic processes. These processes are, however, in operation in Hungary, Czechoslovakia, the German Democratic Republic, and the Federal Republic of Germany. About 15 – 20 t/a of gallium is produced.

Extraction with Chelating Agents. The discovery was made in 1974 that hydroxyquinolines could be used to extract gallium from sodium aluminate liquors (the Rhône-Poulenc process, Fig. 1) [6], these substances having earlier been developed for the hydrometallurgical extraction of copper. The aluminate liquor is brought into contact with a solution of Kelex 100 [*29171-27-5*] in kerosene.Gallium is thereby extracted from the liquor along with aluminum and sodium.Most of the elements extracted with the gallium may be stripped from the extraction medium by treatment with dilute acid. The gallium is then extracted with concentrated acid; either hydrochloric or sulfuric acid may be used. Gallium concentrations of 0.1 – 10 g/L may be reached in the acid extract, depending on the method used. The gallium to aluminum concentration ratio in the extract can reach values as high as 1, which corresponds to enrichment factors of up to 1000 in the primary extraction stage.

Figure 1. Flow diagram showing gallium extraction by the Rhône-Poulenc and Sumitomo processes

Further concentration of the gallium is achieved by anion- or cation-exchange treatment

of the acid extract from the first stage. The metal can be isolated from this concentrate by direct electrolysis.

Although the process solutions are recirculated to a large extent, considerable quantities of waste acid are generated. This waste acid is contaminated with other extracted metals and residues from the extraction media. An important economic factor in the extraction process is therefore the possibility to dispose of these solutions cheaply or to make some use of them.

In the Sumitomo process (Fig. 1) the first stage is extraction with the ion-exchange resin Duolite CS-346 (Diamond Shamrock) [7]. This resin contains amidoxime groups, which form chelate bonds to gallium. Unlike Kelex 100, this resin has the drawback that any vanadium extracted from the aluminate liquors blocks the ion exchange sites. Vanadium must therefore be removed from the circulating liquor of the aluminum oxide plant before gallium extraction. The rest of the Sumitomo process corresponds to the Rhône-Poulenc process.

Gallium is produced by extraction processes in France and Japan.

Purification. The gallium from extraction processes has a purity of 99 – 99.9 wt %. For most applications, however, much higher purities are necessary, reaching 99.999999 % (8N). Various procedures are used to remove the impurities. Volatile metals, such as mercury and zinc, are distilled off under vacuum. Further purification is effected by washing with aqueous acids and alkalies. The purest gallium is obtained by fractional crystallization, zone melting, or single crystal growth. Other methods of purification include the extraction of gallium chloride from acid solution and fractional distillation of liquid gallium compounds.

Environmental Protection. No harmful effects of gallium or its compounds have been reported. There are therefore no regulations concerning gallium concentrations in exhaust gases from gallium manufacturing plants. For the materials used in gallium manufacture, such as mercury or 8-hydroxyquinoline, the relevant legal requirements must be observed.

Quality. The commercially available materials include a crude grade and various pure grades of gallium. The crude metal contains 99 – 99.9 % gallium. The material for semiconductor manufacture is used in purities from 99.9999 % (6N) to 99.999999 % (8N).

Analysis. Gallium is determined in raw materials and partially enriched intermediate products either by complexometric titration (high concentrations) or atomic absorption (low concentrations).

For the analysis of the purest grades of gallium, it is necessary to have methods of determining impurities at parts per million to parts per billion levels. The most important technique is spark source or glow discharge mass spectrometry, which enables heavy metals to be determined with sufficient accuracy. Lighter elements can be determined by activation analysis or by special mass spectrometric techniques.

A general assessment of gallium purity may be made from its residual resistance ratio. This is determined from the electrical conductivity of a gallium single crystal at room temperature and at liquid helium temperature. This ratio is very sensitive to the presence of impurities but is nonspecific. Typical values for high purity gallium are better than 55 000.

6. Storage and Transportation

The low melting point of gallium and the high purity requirements mean that care must be taken to prevent gallium from melting or being contaminated by the packing materials during storage and transportation. The metal is usually sold in lumps of 10 g – 2 kg, individually packed and kept cold in plastic containers.

For short distances, gallium may be carried by truck or rail, provided that the temperature is not allowed to exceed 20 °C. For carriage over long distances, the method chosen is usually air transport, in which uninterrupted cooling is to be maintained. Regulations governing packaging for air transport have been laid down by IATA owing to the ability of gallium to form alloys with aluminum at normal temperatures, these alloys having very low mechanical strength. Gallium must be contained inside seven layers of packing material and in warm weather the container must be cooled. In this way, the danger of an accident in which the structural metal of

the aircraft is attacked by liquid gallium can be reduced. In addition, there is a limit imposed on the amount of gallium which may be carried in an aircraft.

7. Uses

The main use of gallium is as a raw material in the manufacture of semiconductors which are formed by the combination of gallium with elements of group 15 (especially P and As). They have certain advantages over other semiconductor materials: (1) faster operation with lower power consumption, (2) better resistance to radiation and, most importantly, (3) they may be used to convert electrical into optical signals.

The largest proportion of the gallium produced worldwide goes to the manufacture of the arsenide or phosphide for the production of lightemitting diodes (LEDs, → Display Technology; → Electroluminescent Materials and Devices). The manufacture of integrated circuits using gallium arsenide is still at the development stage. A small proportion of the gallium produced is converted into the oxide for manufacture of gallium – gadolinium garnets (GGG) [8]. These are used to produce magnetic bubble memories.

8. Economic Aspects

In 1986, 50 t gallium was used worldwide (Fig. 2), mainly in the manufacture of lightemitting diodes and other optoelectronic components.

Figure 2. World gallium consumption

About 65 % of the market is in Japan, 20 % in the United States, and 15 % in Europe. The price has fallen continuously since 1970 and in 1986 reached $ 450 or 77 000 yen per kg for 6N gallium. The total value of the gallium used worldwide in 1986 was therefore $ 22×10^6 (3.85×10^9 yen). Gallium is extracted in Western Europe, Japan, and several countries of the Eastern Bloc. Production levels in the Soviet Union, the German Democratic Republic, Hungary, and Czechoslovakia are not known exactly as only a small part of the gallium produced there is exported.

The following companies produce gallium: INGAL, (Federal Republic of Germany), Rhône-Poulenc (France), Sumitomo (Japan), and Dowa Mining (Japan). Musto Mining (USA), Eagle Picher (USA), Alcan (Canada), and Cominco (Canada) have ceased production.

In addition to these producers of primary gallium, a number of companies recover pure gallium from gallium scrap.

World gallium production increased from 17 800 kg in 1978 to 46 200 kg in 1984, but decreased to 40 000 kg in 1988 (Table 1).

9. Toxicology and Industrial Medicine

Gallium is only slightly toxic. No industrial injury caused by the metal or its compounds during gallium production and processing has been reported. An investigation in 1984 and 1985 by the Chemical Trade Association did not reveal any evidence of damage to health caused by gallium.

1. Introduction

1.1. Types of Gases; General Overview of Production Methods and Characteristics

Gases for industrial or heating uses can be classified in various ways. The most appropriate classification appears by calorific (heating) value ranges, in kJ/m^3 (STP):

Water and producer gas	4600 – 12 500
Synthesis and reduction gas	ca. 12 500
Town gas and medium-Btu gas	16 700 – 20 000
Biogas and landfill gas	18 000 – 29 000
High-Btu gas and substitute natural gas (SNG)	25 000 – 37 000

A distinction has deliberately been made between *water gas* and *synthesis gas*, although water gas was formerly used in large quantities for synthesis as well. However, the so-called water gases are based on very specific raw materials and belong to a different generation of production methods compared to synthesis gases produced in modern plants. *Reduction gas* refers to gases used in iron production.

Synthesis gas is the basis for most of the hydrogen (→ Hydrogen) produced, and it is also used as a fuel gas, e.g., in gas turbines (see Section 7.3).

Biogas and *landfill gas* (→ Methane) are produced during biological degradation of organic matter. They may be collected and purified either to be used further (renewable energy) or to prevent air pollution.

1.1.1. Water Gas and Producer Gas

The terms water gas and producer gas were first used in solid fuel gasification technology. Both types of gas were very important from the 1920s to the 1940s. They were the basis for producing synthesis gas, town gas, and fuel gas. The technology is of only minor importance today because the raw material basis has shifted largely from solid fuels to liquid and gaseous fuels, and high-performance processes have been developed for coal-based synthesis gas, town gas, and grid gas.

Production of Water Gas. Water gas is usually produced in an alternating operation, i.e., by alternately hot blowing a fuel layer with air and gasifying it with steam. Among its various modifications, the production of so-called *blue water gas* from coke was the most common method, yielding gas with high hydrogen and

carbon monoxide contents which was suitable for use as synthesis gas. By addition of higher hydrocarbons, the calorific value of water gas could be increased (*carbureting*) so it could be used as town gas.

Although most water gas plants were based on coke, plants also operated with anthracite and noncaking highly volatile types of coal (coal water gas or double gas). Coal with a high volatile matter content gives gases with higher calorific values because gasification gas is supplemented by a considerable amount of devolatilization gas.

In the water gas process with its cyclic mode of operation, coke has two functions: (1) it reacts with blowing air during warm-up and with steam during gasification, and (2) serves as a heat regenerator.

Because of the expensive raw material (coke), complicated batch operation, and relatively low output per gasifier (6000 – 9000 m^3 (STP)/h), this method of producing synthesis and town gases has been replaced by more up-to-date processes. The gas production of synthesis gas plants based on either natural gas (in tubular reformers; see Chap. 2) or heavy oil (by partial oxidation; see Chap. 3), and of modern coal gasification plants (see Chap. 4) is ten times higher than that of water gas plants.

Production of Producer Gas. Producer gas is obtained by supplying a gasification agent consisting of air and steam continuously, rather than cyclically, to a gas producer of the same general design as a water gas producer. This gas has a lower calorific value than water gas because it contains atmospheric nitrogen. Producer gas was obtained from a variety of rotary grate gas producers from the 1920s to the 1940s. Because of its high nitrogen content, which cannot be eliminated at economically justifiable cost, this gas is not suitable for use as synthesis gas; it was employed almost exclusively as fuel gas and as an additive to town gases in municipal works.

In addition to coke, noncaking coals were also used as feedstocks, and a few plants were also built for the gasification of caking bituminous coals under atmospheric conditions and under pressure (Lurgi pressure gasification).

Nature of Water Gas and Producer Gas. The following is a typical analysis of a water gas, in percent by volume:

Carbon dioxide	5	Hydrogen	50
Carbon monoxide	40	Nitrogen	5

A typical analysis of a producer gas, in percent by volume, is

Carbon dioxide	5.5	Hydrogen	10.5
Carbon monoxide	29.0	Nitrogen	55.0

The higher heating values (HHV) for water gas based on coke and for producer gas are 10 500 – 12 500 kJ/m^3 (STP) and 4600 – 6700 kJ/m^3 (STP), respectively.

The nitrogen content of water gas, amounting to ca. 5 vol %, does not originate from coke or coal for the most part, but is due to the fact that air remains in the coke pores on transition from the blowing to the gasification period. This nitrogen content can be lowered by discarding a small fraction of the gas produced at the beginning of the gasification period.

1.1.2. Synthesis Gas and Reduction Gas

The gas production method used depends on the raw materials. The raw materials are mainly natural gas, naphtha, heavy vacuum residue, and coal (see Chaps. 2, 3, 4). In addition, unconventional fuels such as solid or liquid waste materials or biomass gain interest. However, in the recent decades most of the world production of synthesis gas was based on natural gas and sulfur-rich heavy vacuum residues. Because of more stringent environmental protection requirements, these residues may no longer be burned in boiler plants in many countries, so their market value is often low. Countries that do not have these two raw materials, particularly countries in which no natural gas is available, often use naphtha. Depending on certain boundary conditions such as the relationship between oil and coal prices, as well as local factors and strategic considerations, plants based on coal will continue to be built.

Production of Synthesis Gas. Because synthesis gas is processed under elevated pressure, a trend toward operating gas production plants at increasingly high pressure could be observed. Gas production at higher pressure reduces the

cost of compressing synthesis gas to the required synthesis pressure.

Natural Gas as Raw Material (Chap. 2). Synthesis gases are produced from natural gas mainly in tubular reformers. If the atural gas contains virtually no nitrogen, a temperature of 750 – 800 °C is sufficient for gas suitable in *ammonia synthesis.* Residual unreacted methane is reformed in a secondary reformer (catalytic partial oxidation with air) with simultaneous adjustment of its nitrogen content.

For normal *methanol synthesis*, reforming is performed in *one step* in a tubular reactor at 850 – 900 °C in order to leave as little methane as possible in the synthesis gas.

For large methanol synthesis plants, Lurgi has introduced a *two-step combination* that gives better results. In the primary tubular reformer, lower temperature (ca. 800 °C) but higher pressure (2.5 – 4.0 MPa instead of 1.5 – 2.5 MPa) are applied. The secondary reformer operates with a fixed catalyst bed as in the case of ammonia synthesis gas, but pure oxygen is used for partial oxidation.

More recently, Lurgi developed another two-step gas production scheme. It is based on catalytic autothermal reforming with an adiabatic prereformer and has economical advantages for very large methanol plants (Section 7.1).

The various tubular reformer designs differ primarily in the method of firing the catalyst-containing tubes (from the side or top, terraced, or from the bottom). Subsequent developments of combined reforming resulted in the integration of the primary and the secondary reforming step in one apparatus using the thermal energy of the effluent of the autothermal process for heating the steam reformer part (M.W. Kellogg, Uhde). Exxon tested the simultaneous reforming and partial oxidation of natural gas in a reactor with fluidized catalyst. Apart from tubular reformer technology with or without a secondary reformer, partial oxidation (in one step) is still used sporadically for reforming natural gas. This can be performed either noncatalytically (Shell, Texaco) or catalytically (Lurgi). The latter is used especially when low ratios of hydrogen to carbon monoxide are required.

Naphtha as Raw Material (Chap. 2). The purity of naphtha allows the use of catalysts. Therefore, the production of synthesis and reduction gases from naphtha is carried out almost exclusively catalytically and at elevated pressure.

Externally heated tubular reformers containing special catalysts are used to produce *hydrogen-rich gases* (e.g., ammonia synthesis). Two processes stand out from the others: they differ in the types of tubular reformers recommended and, primarily, in the type of nickel catalyst used. Topsøe uses a nickel catalyst without alkali; ICI employs one with a definite alkali content.

In future naphtha might replace methanol as a raw material for hydrogen produced on board of vehicles driven by *fuel cells*. Due to the much smaller size of such production units as compared with plants in the petrochemical industry and due to restrictions by volume and by utilities (e.g., steam and water), the production scheme and above all the reactors and heat exchangers for naphtha reforming in vehicles look rather different.

Apart from single-stage tubular reforming, two-stage processes have also proved successful for the production of *gases rich in carbon monoxide*, such as those required for methanol and oxo synthesis. An example of a two-stage process is the Recatro process, developed by BASF – Lurgi. Here, naphtha is converted with relatively little steam in an initial low-temperature adiabatic stage over a special nickel catalyst to produce a rich gas containing ca. 60 – 65 vol % methane plus hydrogen and carbon dioxide. This gas is supplied together with the remaining steam to a conventional tubular reformer to be reformed to carbon monoxide-rich synthesis gas in the presence of a conventional catalyst. The two-stage operation makes carbon dioxide recycling unnecessary in many cases or reduces it considerably.

A few plants using partial oxidation with (Lurgi) or without (Shell, Texaco) catalysts have been built.

Heavy Fuel or Residual Oil as Raw Material (Chap. 2). For the production of synthesis and reduction gases from heavy and residual oils, two processes are accepted worldwide: the Shell and the Texaco process, both operating under elevated pressure and noncatalytic. The Texaco process was originally designed for partial oxidation of natural gas; the Shell process, developed later, was tailored from the beginning to gasification of heavy oil. The differences bet-

ween the two processes are virtually negligible and involve only details of equipment design.

Coal as Raw Material (Chap. 4). Processes employing coal that are used in practice operate on a noncatalytic basis. Various processes operating under *elevated pressure* are available: Lurgi, BGL (British Gas/Lurgi), HTW (High Temperature Winkler), U-Gas, Texaco, Shell and Prenflo. The Koppers – Totzek process and the original Winkler process operate at *atmospheric pressure.* Coal gasification plants for the production of synthesis gas built since the 1950s are based essentially on the Koppers or Lurgi processes.

In view of the distribution of fossil fuels in the world — almost ten times as much coal exists as petroleum and natural gas, and it is distributed relatively uniformly — and the sharp increase in oil prices in the 1970s, efforts have been made in many countries to develop new coal gasification processes tailored to the requirements of particular countries and their coal deposits.

In most processes, the heat required for gasification is provided by partial oxidation with pure oxygen. These processes are based essentially on the following three process arrangements:

1) moving bed,
2) one or more fluidized beds, and
3) entrained-flow systems in which coal dust and the gasification agent are conveyed cocurrently.

Combinations of these three process arrangements are being investigated, as are processes applying high-temperature melts.

The overall arrangement of various coal gasification plants, including downstream units, is determined essentially by the composition of the raw gases. The gases produced at increased pressure by the Lurgi and by the BGL gasification processes contain methane, which can be converted to carbon monoxide and hydrogen for downstream ammonia or methanol synthesis, or can be removed before entering the high-pressure compressor. The Koppers – Totzek, the Texaco, as well as the other entrained-flow processes yield a gas without methane, but with a higher specific oxygen consumption. As in all high-temperature gasification processes, gas from the latter two processes has a high carbon monoxide content, requiring considerable conversion measures for certain syntheses. The gasification processes applied to coal are also suitable for petrol coke if they can cope with its low reactivity and they are also applied when biomass or waste materials are used as fuels.

Production of Reduction Gas. In principle, reduction gas production is very similar to that of synthesis gas. However, iron ore is usually reduced under atmospheric conditions, so reduction gas can be produced at atmospheric or slightly increased pressure. Reduction gases used for the production of sponge iron by various direct reduction processes (→ Iron, Chap. 2.6) must meet certain requirements. Generally, the proportion of oxidizing components such as steam and carbon dioxide in the gas mixture produced should be as low as possible, always $< 10\,\%$. This goal can be achieved by cooling the gases produced from coal, oil, naphtha, or natural gas and removing carbon dioxide. However, because reduction gases in the shaft furnaces of steel works are needed at high temperature, more cost-effective solutions are being sought and used. In the *Midrex process* natural gas is converted at ca. 1000 °C in the tubular reformer, without the addition of steam, thereby producing only hydrogen and carbon monoxide; the conversion is such that the reformed gases can be used directly in the shaft furnace.

As the recovery of byproducts from coke oven raw gas (benzene, phenol) loses economical attractiveness, reduction gas is considered to be produced from coke oven raw gas by catalytic partial oxidation.

Composition and Aftertreatment. Synthesis gas requirements depend on the intended application.

Ammonia synthesis units now generally operate between 13.0 and 22.0 MPa and require gas with a hydrogen: nitrogen ratio of 3: 1. Impurities are limited in modern processes to < 1 ppm for sulfur and 2 – 10 ppm for oxygen-containing components such as oxygen itself, carbon dioxide, and water. With a view to the economy of synthesis (i.e., the purge gas quantities to be branched off), the methane content of synthesis gas must not exceed 0.5 – 0.8 vol %.

This means that the reformer and gasification gases produced from various raw materials must be conditioned appropriately. If the methane content is originally considerably high it can

be lowered by secondary reforming with oxygen or air. Because all reformed gases contain carbon monoxide, they have to be converted, irrespective of the raw materials from which they are produced; this is done by catalytically reacting carbon monoxide with steam to form hydrogen and carbon dioxide (shift conversion). Depending on its residual content after shift conversion, either the carbon monoxide concentration must be lowered (to the ppm range) in a methanation stage or it must be removed at low temperatures by a liquid nitrogen wash. Hydrogen sulfide, organic sulfur compounds, and carbon dioxide have to be removed by appropriate washing procedures.

Similar conditioning and purification processes have to be applied for the production of hydrogen for *fuel cells* (→ Fuel Cells).

Methanol is generated from carbon monoxide as well as from carbon dioxide:

$$2\,H_2 + CO \rightleftharpoons CH_3OH$$

$$3\,H_2 + CO_2 \rightleftharpoons CH_3OH + H_2O$$

The preferred reaction path goes via carbon monoxide, some carbon dioxide is required for kinetic reasons. The ratio $(c_{H_2} - c_{CO_2})/(c_{CO} + c_{CO_2})$ should generally be between 2.0 and 2.2. The theoretical value derived from adding both reaction equations after pondering each of them arbitrarily is 2.0. A higher carbon monoxide content is required for fuel methanol synthesis (Lurgi Octamix and others), in which a mixture of methanol and higher alcohols is produced as an additive to motor fuel. For high-pressure methanol synthesis (35.0 MPa), which is still used in a few cases, the presence of methane adds an economic burden (as in ammonia synthesis). It is less important in low-pressure (5.0 – 10.0 MPa) methanol synthesis (ICI, Lurgi) because compression costs for this gas component are practically negligible because of the lower compression ratio required. The content of sulfur compounds in the gas used for low-pressure methanol synthesis, which is based on a special copper-containing catalyst, must be extremely low. The amount of hydrogen sulfide and organic sulfur compounds in the synthesis gas produced from raw materials with relatively high sulfur content can be lowered to ca. 0.1 ppm by special processes (Rectisol for coal and oil gasification gases; hydrogenation of the organic sulfur compounds in the presence of Comox and Nimox catalysts, and subsequent adsorption prior to the reforming of naphtha and natural gas in the tubular reformer).

Purities applicable in methanol synthesis are also required for *oxo synthesis*. However, because the latter often requires a hydrogen: carbon monoxide ratio of ca. 1: 1, the carbon: hydrogen ratio of the feedstock may require that carbon dioxide be recycled or fed to the gasification unit.

For iron ore *reduction gas*, the sulfur content must be reduced to a few parts per million. Table 1 shows typical analysis data for raw gases from various starting materials.

Table 1. Typical raw gas analyses

Feedstocks and processes	Content, vol %						
	H_2	CO	CH_4	C_{2+}	N_2+ Ar	CO_2	H_2S + COS

1.1.3. Town Gas and Medium-Btu Gas

Because natural gas (→ Natural Gas) has become the preferred fuel gas for households and industry, the production of town and medium-Btu gas from coal and liquid fuels is of minor importance today. High-temperature coking — formerly general practice in town gas works — has disappeared almost completely (→ Coal Pyrolysis). The following is a brief outline of gasification processes for the production of town gas.

Basis of Production. When charcoal was replaced in the last century by coke from bituminous coal to smelt iron in blast furnaces, large quantities of degasification gas were produced by the carbonization of caking coals. Initially, these gases were largely flared; later on, they were distributed through piping systems supplying gas particularly to the municipalities in the

neighborhood of steelworks. The gas grids were large enough to provide sufficient gas from the coke ovens even at times of peak demand; on Sundays and holidays, the gas was flared in the coking plants.

With the increasing demand for grid gas, utilization of the gas system improved, so that towns had to build their own gas production facilities to meet peak requirements. These facilities were based mainly on water gas, which in some cases was carbureted.

Both solid and liquid or gaseous fuels were used as raw materials for town gas production. Liquid hydrocarbons such as fuel oil and, later on, naphtha were preferred, but coal was also used.

Plants using fuel oil are based mainly on a cyclic process arrangement and became very successful since the 1950s. Some of them use straight thermal processes without catalysts, but most employ a catalyst bed. During a blowing phase, a bed of catalytic or noncatalytic material is heated by the combustion of fuel oil with air. After switching to the gasification period, fuel oil is passed over the hot bed along with steam. The ONIA GEGI and SEGAS processes and the Koppers Cowper process have become widely known [1].

The disadvantages of these cyclic processes are their relatively low output and difficulties caused by excessive wear of the switchover mechanism. In addition, as environmental laws tightened toward the end of the 1950s and beginning of the 1960s, plant operators turned to processes using lighter hydrocarbons and continuous operation. The development of special catalysts (ICI, Topsøe) permitted gas production from readily available liquid feedstocks (such as lighter hydrocarbons and naphtha having a boiling end point up to 200 °C) to be carried out in externally heated tubular reformers. Apart from its higher efficiency, this mode of operation had an additional advantage because the gases produced were available at increased pressure, thus reducing the expenditure for their distribution in pressure gas systems. The methane content of the gases could be increased by keeping reaction temperatures in the tubular reformer low, so that after a cold carbureting stage with propane – butane, standard town gas could be produced.

Cold carbureting was often not applicable because either propane – butane was not available at a reasonable price, or certain standards with respect to dew-point were not met, therefore, modified processes aiming at increased production of methane from naphtha (BASF/Lurgi, British Gas, Japan Gasoline Corp.) were developed. Because methane content increases with decreasing temperature according to thermodynamic equilibrium, appropriate catalysts had to be developed. In these processes, a so-called *rich gas* having a methane content of ca. 65 vol % is produced from naphtha and steam by a slightly exothermic reaction in a shaft reactor at 400 – 490 °C. Because the calorific value and specific gravity of this gas are too high, compared with pertinent standards for town gas, part of it must be reformed in a downstream tubular reformer using commercial catalysts and then remixed with the residual methane-rich gas. Another method of obtaining a leaner gas is to add nitrogen or air. Many European cities built plants of this type with town gas capacities up to 1×10^6 m^3 (STP)/d.

Plants that converted propane – butane to town gas via externally heated tubular reformers were built particularly for small capacities. Part of the propane – butane was added to increase the calorific value of the reformed gas after carbon monoxide shift conversion. A few plants produced town gas by reforming natural gas in externally heated tubular reformers for transitional periods. This was done mainly when the consumers' existing piping systems and burners were to be used, even if a loss in efficiency had to be accepted in converting natural gas to town gas.

Oil gasification by partial oxidation (Shell, Texaco, Lurgi; see Section 3.2.2) has not become important in town gas production because of the high investment cost of such plants. The gases produced, consisting essentially of hydrogen and carbon monoxide must be carbureted to comply with standards.

Along with the development of gas production processes, downstream gas conditioning and gas cleaning units were adapted as well. Carbon monoxide shift conversion plants often reduced the carbon monoxide content to < 3 vol %, sometimes even to < 1 vol %, to eliminate the danger of poisoning.

The *composition* of town and grid gas is given in Tables 42 and 43 (Chap. 8). Group A in these tables corresponds to town gas; Group B, to grid

gas; and the first gas family, to town and grid gases combined.

1.1.4. Biogas and Landfill Gas (→ Methane)

Biogas is the gaseous reaction product from anaerobic digestion of wastewater having a high BOD value or of sludge from wastewater treatment plants. It is used solely as fuel for combustion engines to meet the power requirements of the treatment plant.

Landfill gas is produced by the degradation of organic matter in the waste disposed of in landfills under anaerobic conditions. Because access to oxygen is not strictly controllable, aerobic degradation may occur simultaneously, producing water and carbon dioxide. Landfill gas is recovered via pipelines buried in the landfill. For existing landfills, wells are drilled and lined with tubes to allow the gases to be extracted. Landfill gas is used mostly as fuel gas for cogeneration and in combustion engines after suitable purification.

Composition. Biogas is composed of 60 – 70 vol % methane and 30 – 40 vol % carbon dioxide, depending on the feed and digester temperature (mesophilic – thermophilic).

Landfill gas is composed of 50 – 55 vol % methane, 41 – 45 vol % carbon dioxide, and 1 – 4 vol % nitrogen.

Depending on the nature of landfill waste, the gas may also contain considerable amounts of halocarbons.

1.1.5. Rich Gas and Substitute Natural Gas (SNG)

Basis of Production. As a result of the doubts concerning gas supplies and their availability to the industrial nations in the 1970s efforts were made to produce synthetic natural gas from the plentiful coal supplies. These efforts were feasible where natural gas accounted for a high percentage of primary energy and cheap domestic coal was available. Thus, a plant was built in North Dakota (United States) which has gone into operation in 1984, producing ca. 3.9 $\times 10^6$ m^3 (STP)/d of SNG from lignite. In this plant, lignite is gasified in Lurgi pressure gasifiers, and the methane content required is adjusted by reacting carbon monoxide and hydrogen from the raw gas in a methanation stage downstream of the gas cleaning unit. In addition, the Lurgi gasification process has been developed further to produce SNG more economically by increasing gasification pressure to 10.0 MPa (Ruhr 100, see Section 4.4). Here, more than 50 vol % of methane recoverable from coal is produced in the gasification stage proper.

Heavy vacuum residues can also be used as feedstock for SNG production. However, as in coal-based plants, capital investment is relatively high. The discovery of huge new natural gas resources in some areas of the world during the past few years has made the production of SNG less attractive.

Composition. *Rich gases* have a higher calorific value than grid gas, with gross calorific values from about 25 000 kJ/m^3 (STP) upward. A rich gas produced from naphtha (British Gas or BASF – Lurgi process) has the following typical analysis, in percent by volume:

Carbon dioxide	21.6	Hydrogen	12.5
Carbon monoxide	0.3	Methane	65.6

Substitute natural gas should differ as little as possible from natural gas. It must be conditioned so that it can be substituted for natural gas. This depends on the following parameters: higher heating value, density, and Wobbe index (see Section 8.2.1.3).

In addition the specified content of impurities, particularly sulfur, must not be exceeded. Typical SNG produced in a coal gasification plant in North Dakota has the following analysis, in percent by volume (unless otherwise stipulated):

Methane	96.3	Nitrogen + argon	1.1
Carbon monoxide	0.02	Carbon dioxide	1.2
Hydrogen	1.38	Hydrogen sulfide	4 ppm

1.2. Raw Materials for Gasification

Gaseous Fuels. Natural gas as raw material is of paramount importance for gasification or reforming (the term reforming is used more

commonly for gases) in externally heated tubular reformers to yield synthesis gas for various applications. Plants also reform natural gas by partial oxidation. The composition of natural gases is not important for the technology to be applied, as long as their inerts content is negligible. However, if the nitrogen content rises above 5 – 10 vol %, this may have consequences for the design of ammonia synthesis gas plants operated on the tubular reformer principle.

In certain new energy scenarios, natural gas still plays an important role. Thus, the energy required for natural gas reforming may be supplied — at least partially — by solar collectors or high-temperature nuclear reactors. Liquid motor fuels can be synthesized from synthesis gas. In this way, thermal energy, which is difficult to store and utilize, is converted to energy carriers better adapted to the requirements.

Coke oven gas (→ Coal Pyrolysis) is of minor importance for producing synthesis gas because special expenditures are necessary to remove various impurities from the coke oven gas, and compression costs are high. In older plants, coke oven gas was separated into its individual components by fractionated condensation and distillation at low temperature rather than being reformed (the content of methane and higher hydrocarbons is low anyway); these components were then used for synthesis gas production.

Liquid Fuels. In most cases, various fractions of crude oil are used for gasification. Only in very rare cases is unrefined crude oil used directly for gasification because neither its economic nor its technical considerations are optimum.

Liquefied petroleum gas (LPG, a propane – butane mixture; → Liquefied Petroleum Gas) is used for the production of town gas, particularly in smaller capacity plants, and for peak shaving. It is virtually sulfur-free and can be processed without significant problems. *Light naphtha* is utilized for larger town gas plants and for the production of synthesis gas. Generally, fractions boiling at 40 – 110 °C are used, but full-range *straight-run naphtha* with a boiling end point of 150 – 200 °C may also be employed. Depending on its origin, this naphtha has a sulfur content between 30 and 300 ppm. Naphtha must be completely desulfurized because almost all conventional processes for the production of town or synthesis gas include a reaction stage involving catalysts that are very sensitive to sulfur poisoning.

In some cases, LPG and naphtha have also been converted to town and synthesis gas by partial oxidation (thermally or catalytically) with oxygen or oxygen-enriched air. For catalytic partial oxidation, desulfurization to 20 – 50 ppm is sufficient.

Synthesis gas is produced from *high-boiling residues* by partial oxidation with oxygen. Originally, the high-boiling fraction (initial boiling point above 350 °C) from atmospheric distillation units of refineries (→ Oil Refining) — the heavy fuel oil — was used for this purpose. To date even higher viscosity fractions from vacuum distillation and conversion plants are being used increasingly. Because of the more stringent requirements imposed by environmental legislation, these heavy oils can no longer be burned in boiler houses and are, therefore, cheap raw materials for gasification, which also eliminates various pollutants in the residue such as sulfur and heavy metals. To be used in gasification plants, the heavy oil must be suitable for pumping and spraying. Therefore, the oils are preheated to attain the required viscosity.

The ash content of the heavy oils and the composition of the ash affect the operating temperature of gasification plants and the service life of the refractory lining. Vanadium and nickel in ash are particularly harmful.

Apart from petroleum fractions, other liquid fuels may be used for gasification, although they are not very important. These include:

1) tars from bituminous coal and lignite for gasification by partial oxidation;
2) fractions from shale oil (→ Oil Shale) production, particularly heavy fractions, for gasification by partial oxidation;
3) methanol for producing peak shaving gas in catalytic town gas plants;
4) hydrocarbon condensates from natural gas production for gasification by partial oxidation; and
5) waste from chemical plants (e.g., isobutyraldehyde).

Purity Requirements for Liquid and Gaseous Fuels. Raw materials for gasification plants using catalysts must generally be very

pure. Therefore, in most cases, such plants are equipped with special upstream purification units. A certain tolerance regarding the content of impurities can be accepted in cyclic processes that regenerate catalysts in the respective cycles. However, continuous processes important to modern technology require exceptionally pure fuels, especially with respect to sulfur compounds. Catalysts used for these processes thus permit the use only of gaseous fuels (natural gas) and of liquid hydrocarbons up to a boiling end point of ca. 200 °C.

Generally, the lower the operating temperature of the catalytic process, the lower is the residual sulfur content that can be tolerated in the raw materials. How adverse an effect sulfur compounds in the gas have on the active sites of catalysts can be derived from equilibrium conditions governing the reaction of the metallic phase of the catalyst with the sulfur compounds. Most gasification catalysts contain nickel as an active substance. At constant partial pressure of sulfur compounds in the gas, nickel sulfide formation increases with decreasing temperature; a sulfided catalyst no longer provides the desired results regarding reaction direction (danger of carbon formation), speed, and selectivity.

Therefore, light hydrocarbons are desulfurized to < 0.1 ppm of sulfur upstream of plants operated at low catalyst temperature (400 – 700 °C). The sulfur content may often be higher by one or two orders of magnitude in catalytic processes operating above 850 °C.

Solid Fuels. Various solid fuels are not all equally suitable for gasification. In addition, different gasification processes have different fuel requirements.

Because endothermic gasification reactions should be as complete as possible, the suitability of solid fuels for gasification improves as their reactivity increases. This reactivity can be correlated with the oxygen content, which decreases with increasing carbonization (i.e., with increasing age of the fuel).

The classification and designation of various types of coal are different in individual industrial countries (→ Coal, Chap. 4). As a rule, however, they depend on volatile matter, which almost always means classification by age of the coal.

Additionally, the following properties of fuels are essential for assessing their suitability for gasification:

Ash content	Coal grain size
Water content	Melting behavior of the ash
Sulfur content	Behavior of the coals on heating
Caking properties	

Because coal gasification adds considerably to the costs of upgraded energy (i.e., the gas), coal used for this purpose should be as cheap as possible. Wherever possible, only coal that is not suitable for other applications and, therefore, has a low market price should be used. Coal produced by open-pit mining is of special interest for gasification.

Almost all solid fuel such as wood, peat, lignite, young and old bituminous coal, and coke, including petrol coke, has been used for gasification. In the future, more use should be made of lignites and younger noncaking or caking bituminous coal, as well as coal with a high ash content (20 – 50 wt %) or sulfur-rich coal which is rarely suitable for other applications.

With regard to various types of petrol coke (delayed, fluid, Lurgi – Ruhr gas (LR) coke, → Oil Shale,), their high sulfur and heavy-metal content (→ Petroleum Coke) renders combustion increasingly difficult in view of pollution control measures. Petrol coke is, therefore, turning into a new potential raw material for gasification.

Gasification of wood has been revived because of increasing interest in renewable raw materials. Emphasis is mainly on the production of clean fuel gas (low sulfur content of wood), but synthesis gas production is also possible with modern fluidized-bed processes.

Suitability of Fuels for Gasification. Considerable differences exist in the complexity of gasification technology applied, depending on whether solid, liquid, or gaseous fuels are used. A general rule is that capital cost and consumption figures are higher for solid than for liquid fuels, and for liquid higher than for gaseous fuels. Therefore, in the production of particular gases, mere comparison of specific energy prices of various fuels is insufficient; individual costs for gasification must be considered as well (see Table 2).

Table 2. Comparison of capital cost and energy requirements for an ammonia plant and a methanol plant with a capacity of 1000 t/d based on gaseous, liquid, and solid fuel

	Natural gas	Heavy oil	Coal
Ammonia plant			
Capital cost, %	100	170	225
Energy requirements, %	100	115	135
Methanol plant			
Capital cost, %	90	150	200
Energy requirements, %	95	105	125

To make end products competitive, the specific energy price of coal must be lower than that of heavy oil, and the latter must be lower than that of natural gas. In principle, this also applies to other solid and liquid fuels with regard to the complexity of the conversion plant based on these particular feedstocks.

Even if fuels of the same physical state are compared, great differences exist in the properties of individual substances, which also affect their suitability for gasification.

1.3. Physicochemical Basis for Gas Production

Gasification can be described by overall chemical reactions, from which conclusions may be drawn regarding the conversion of materials and heat of reaction.

Gasification of solid and liquid fuels involves heterogeneous reactions at the phase boundary of particles or droplets and homogeneous reactions in the gas phase. The latter include reactions of components that devolatilize at operating temperature.

The following principles form the basis for calculating gasification processes:

1) *Material Balance.* In establishing a material balance, the total number of atoms of the individual elements in the reactants is equalized to that in the products, irrespective of the distribution of the elements between the individual components (principle of conservation of mass).
2) *Energy Balance.* Energy balance is based on the principle of conservation of energy. Consequently, energy supplied to the system (enthalpy of reactants and heat supplied) is equal to energy removed from it (enthalpy of products and heat removed). In determining enthalpy, formation and phase change energies must be considered.
3) *Chemical Equilibrium.* The equilibrium composition of the gasification product is determined by the temperature-dependent equilibrium constants of reactions going on in the system and by the operating pressure.
4) *Chemical Kinetics.* Because equilibrium is not attained when residence time is too short (for example, because the temperature is too low), the composition of the gasification product in this case is determined by the kinetics of the reactions. In addition, transport phenomena, such as boundary layer or pore diffusion, may have some influence (see page 15.

Practical calculation leads to nonlinear equation systems in which the number of unknown quantities is determined essentially by the number of components in the raw gas. The solution may be found iteratively or — if appropriate routines are used — simultaneously. Calculations are particularly complicated when chemical kinetics must be considered.

Reaction Enthalpy of Gasification. Gasification reactions can be described by many different equations. To calculate the reaction enthalpy of gasification, however, a limitation to certain characteristic reaction groups is sufficient. The reaction enthalpy of all other reactions can be derived by combining these basic equations, and individual reactions have no influence on the total heat balance of a sequence of reactions if the same feedstocks are turned into the same products (Hess's law).

The reaction groups characteristic of gasification can be subdivided as follows (ΔH refers to 0 °C and 0.1 MPa as reference state; ΔH is negative for exothermic reactions and positive for endothermic reactions):

1) *Reactions with molecular oxygen* (*combustion*)

$$\mathrm{C}+1/2\,\mathrm{O_2} \rightleftharpoons \mathrm{CO}\ \Delta H = -110.62\,\mathrm{kJ/mol} \quad (1)$$

$$\mathrm{CO}+1/2\,\mathrm{O_2} \rightleftharpoons \mathrm{CO_2}\ \Delta H = -283.15\,\mathrm{kJ/mol} \quad (2)$$

$$\mathrm{H_2}+1/2\,\mathrm{O_2} \rightleftharpoons \mathrm{H_2O}\ \Delta H = -242.00\,\mathrm{kJ/mol} \quad (3)$$

$$\mathrm{C}_n\mathrm{H}_m+(n+m/4)\ \mathrm{O_2} \rightleftharpoons n\,\mathrm{CO_2}+m/2\,\mathrm{H_2O} \quad (4)$$

For example,

$$CH_4 + 2\,O_2 \rightleftharpoons CO_2 + 2\,H_2O \quad \Delta H = -802.86\,\mathrm{kJ/mol} \tag{4a}$$

$$C_2H_6 + 7/2\,O_2 \rightleftharpoons 2\,CO_2 + 3\,H_2O \quad \Delta H = -1428.8\,\mathrm{kJ/mol} \tag{4b}$$

$$C_3H_8 + 5\,O_2 \rightleftharpoons 3\,CO_2 + 4\,H_2O \quad \Delta H = -2045.4\,\mathrm{kJ/mol} \tag{4c}$$

The reaction enthalpy of combustion of other gaseous or liquid fuels is described in the literature (e.g., [2 – 4]).
For *partial combustion* of gaseous or liquid fuels to carbon monoxide and steam,

$$C_nH_m + (n/2 + m/4)\,O_2 \rightleftharpoons n\,CO + m/2\,H_2O \tag{5}$$

the reaction enthalpy can be calculated from the enthalpies of Equations (4) and (2) as follows:

$$\Delta H\,(\mathrm{Eq.\,5}) = \Delta H\,(\mathrm{Eq.\,4}) - n\,\Delta H \tag{Eq. 2}$$

2) *Reactions with steam*

$$C + H_2O \rightleftharpoons CO + H_2 \quad \Delta H = +131.38\,\mathrm{kJ/mol} \tag{6}$$

$$CO + H_2O \rightleftharpoons CO_2 + H_2 \quad \Delta H = -41.16\,\mathrm{kJ/mol} \tag{7}$$

(homogeneous water gas reaction, shift conversion)

$$C_nH_m + n\,H_2O \rightleftharpoons n\,CO + (m/2 + n)\,H_2 \tag{8}$$

For example,

$$CH_4 + H_2O \rightleftharpoons CO + 3\,H_2 \quad \Delta H = +206.28\,\mathrm{kJ/mol} \tag{8a}$$

$$C_2H_6 + 2\,H_2O \rightleftharpoons 2\,CO + 5\,H_2 \quad \Delta H = +347.50\,\mathrm{kJ/mol} \tag{8b}$$

$$C_3H_8 + 3\,H_2O \rightleftharpoons 3\,CO + 7\,H_2 \quad \Delta H = +498.06\,\mathrm{kJ/mol} \tag{8c}$$

The enthalpy of the reaction of fuels with steam to produce carbon dioxide and hydrogen

$$C_nH_m + 2\,n\,H_2O \rightleftharpoons n\,CO_2 + (m/2 + 2\,n)\,H_2 \tag{9}$$

can be determined by

$$\Delta H\,(\mathrm{Eq.\,9}) = \Delta H\,(\mathrm{Eq.\,8}) + n\,\Delta H \tag{Eq. 7}$$

because Equation (9) may be considered a combination of Equations (8) and (7).

3) *Reactions with carbon dioxide*

$$C + CO_2 \rightleftharpoons 2\,CO \quad \Delta H = +172.54\,\mathrm{kJ/mol} \tag{10}$$

(Boudouard reaction)

$$C_nH_m + n\,CO_2 \rightleftharpoons 2\,n\,CO + m/2\,H_2 \tag{11}$$

For example,

$$CH_4 + CO_2 \rightleftharpoons 2\,CO + 2\,H_2 \quad \Delta H = +247.44\,\mathrm{kJ/mol} \tag{11a}$$

$$C_2H_6 + 2\,CO_2 \rightleftharpoons 4\,CO + 3\,H_2 \quad \Delta H = +429.82\,\mathrm{kJ/mol} \tag{11b}$$

$$C_3H_8 + 3\,CO_2 \rightleftharpoons 6\,CO + 4\,H_2 \quad \Delta H = +621.53\,\mathrm{kJ/mol} \tag{11c}$$

Generally, the reaction enthalpies for hydrocarbon gasification with carbon dioxide (Eq. 11) are obtained from the enthalpies of Equations (8) and (7) as follows:

$$\Delta H\,(\mathrm{Eq.\,11}) = \Delta H\,(\mathrm{Eq.\,8}) - n\,\Delta H \tag{Eq. 7}$$

4) *Hydrocarbon decomposition reactions* (*soot formation*)
Hydrocarbon decomposition is described by

$$C_nH_m \rightleftharpoons n\,C + m/2\,H_2 \tag{12}$$

For example,

$$CH_4 \rightleftharpoons C + 2\,H_2 \quad \Delta H = +74.91\,\mathrm{kJ/mol} \tag{12a}$$

$$C_2H_6 \rightleftharpoons 2\,C + 3\,H_2 \quad \Delta H = +84.74\,\mathrm{kJ/mol} \tag{12b}$$

$$C_3H_8 \rightleftharpoons 3\,C + 4\,H_2 \quad \Delta H = +103.92\,\mathrm{kJ/mol} \tag{12c}$$

may be considered the reverse of hydrocarbon formation from its elements and is essential for the gasification of hydrocarbons.
The reaction enthalpy can be calculated from the combustion enthalpies of the reactants:

$$\Delta H\,(\text{Eq. 12}) = \Delta H\,(\text{Eq. 4}) - n\,\Delta H\,(\text{Eq. 1}) - n\Delta H\,(\text{Eq. 2}) - m/2\,\Delta H\,(\text{Eq. 3})$$

In calculating the main gas components, side reactions of sulfur compounds (H_2S, COS, etc.) and nitrogen compounds (NH_3, HCN) are generally neglected because they have no great effect on the numerical distribution of the main gas components. If detailed information on the distribution of secondary components is required, further calculations can be made and the results used for the main gas components.

Chemical Equilibrium. The gasification reactions represented by Equations (1) – (12) are never complete in either of the two possible directions but tend to reach an equilibrium expressed by the equilibrium constant K_p. For Equation (8 a), for example, this constant is given by

$$K_p = \frac{p_{\mathrm{CO}} \cdot p_{\mathrm{H_2}}^3}{p_{\mathrm{CH_4}} \cdot p_{\mathrm{H_2O}}} = \frac{x_{\mathrm{CO}} \cdot x_{\mathrm{H_2}}^3}{x_{\mathrm{CH_4}} \cdot x_{\mathrm{H_2O}}} P^2 = f\,(T)$$

where x_i represents the mole fraction and p_i the partial pressure of each of the four components, P the total pressure, and T the temperature.

For Equation (7), the carbon monoxide shift conversion (which in nearly any case has to be considered) the equilibrium constant is given by

$$K_p = \frac{p_{\mathrm{CO_2}} \cdot p_{\mathrm{H_2}}}{p_{\mathrm{CO}} \cdot p_{\mathrm{H_2O}}} = \frac{x_{\mathrm{CO_2}} \cdot x_{\mathrm{H_2}}}{x_{\mathrm{CO}} \cdot x_{\mathrm{H_2O}}} = f\,(T)$$

In comparison to the steam reforming reaction (8 a) the equilibrium composition of the shift conversion is not influenced by the total pressure, because simply spoken, the number of molecules on the right and on the left side of Equation (7) is identical. The temperature dependence of the equilibrium constant (log K_p vs. $1/T$) is shown in Figure 1.

According to the laws of thermodynamics, the equilibrium constant K_p of a reaction can be calculated by means of the Gibbs free energy of the reaction or the free formation energies of the reactants.

Figure 1. Water gas equilibrium, $K_p = f\,(1000/T)$

Strictly speaking, the equilibrium constant K_p in the above form applies only to ideal gases. At increased pressure (total of ca. 1.0 MPa or more) and near the boiling points of the liquids, the appropriate partial fugacities should be used instead of partial pressures. These fugacities allow for the real behavior of individual gas components. However, in practice, partial pressures can be used for the calculation with sufficient accuracy in most cases.

In heterogeneous reactions, partial pressures of the solids are not taken into account because they are regarded as a function of temperature alone, which is included in the equilibrium constant K_p. However, the free formation energy of the solids must be considered in a thermodynamic calculation of the equilibrium constants.

The three reactions described by Equations (7), (8 a) and (10) are almost always sufficient to calculate the theoretical product gas composition of various gasification processes. Table 3 shows the equilibrium constants of these three reactions at different temperatures. In addition equilibrium constants for heterogeneous methane decomposition (Eq. 12 a) are given as an example of hydrocarbon decomposition. This equilibrium may also be derived from Equations (7), (8 a), and (10). Additionally equilibrium constants for COS hydrogenation and hydrolysis are included (see Section 5.2).

$$\mathrm{COS + H_2 \rightleftharpoons H_2S + CO}\qquad \mathrm{COS + H_2O \rightleftharpoons H_2S + CO_2}$$

The temperature dependence of the equilibrium constants can be calculated with an equation of the following type

Table 3. Temperature-dependent equilibrium constants of various reactions

Equation	(7)	(8 a)	(10)	(12 a)	COS hydrogenation	COS hydrolysis
Unit for K_p		bar^2	bar	bar		
Temperature, °C						
100					12.4	4.39×10^4
200					19.1	4.26×10^3
300	38.5	6.13×10^{-8}	3.60×10^{-7}	4.36×10^{-3}	24.4	940
400	11.5	5.54×10^{-5}	8.55×10^{-5}	5.56×10^{-2}	28.0	323
500	4.82	9.16×10^{-3}	4.99×10^{-3}	3.76×10^{-1}	30.3	146
600	2.51	4.88×10^{-1}	1.16×10^{-1}	1.66	31.5	79.1
700	1.52	11.8	1.42	5.41	32.1	48.7
800	1.02	159	11.0	14.1	32.2	32.9
900	7.41×10^{-1}	1.38×10^3	59.8	31.2	32.0	23.7
1000	5.71×10^{-1}	8.63×10^3	249	60.6		
1100	4.60×10^{-1}	4.12×10^4	845			
1200	3.84×10^{-1}	1.59×10^5	2.43×10^3			
1300	3.30×10^{-1}	5.16×10^5	6.08×10^3			
1400	2.91×10^{-1}	1.48×10^6	1.36×10^4			
1500	2.61×10^{-1}	3.69×10^6	2.79×10^4

A general assessment of tendencies in gasification reactions is facilitated by the Le Châtelier – Braun principle that a system in equilibrium tries to evade a change forced upon it. For example, in Equation (8 a), an increase in total pressure results in increased methane formation because the number of gaseous molecules on the right side of Equation (8 a) is higher than that on the left. A pressure increase in reactions proceeding without a change in the number of molecules, such as the homogeneous water gas reaction (Eq. 7) has almost no effect.

Reaction Sequence for Various Gasification Processes. No statements can be made on the basis of thermodynamics regarding the chronological sequence of gasification reactions. Calculations must include reaction kinetics. Frequently, however, the required data are not available. Approximation methods must then be used to calculate product gas composition. A common method involves use of K_p values which, according to experience, reflect the actual final state but pertain to a temperature other than that prevailing at the end of the reactor.

Some processes employ catalysts to accelerate the reaction and enhance reaction kinetics in order to approach equilibrium. Selective catalysts promote desirable reactions at the expense of undesirable ones (e.g., carbon formation according to Boudouard). Generally, reaction rate increases as temperature increases. Gasification,

therefore, approaches equilibrium more easily at higher than at lower temperature.

Tubular Reactor Reforming. When reforming hydrocarbons, especially methane, in externally heated tubular reactors, conversion of the hydrocarbons with steam to yield carbon oxides and hydrogen (according to Eqs. 8 and 9) must be considered basic reactions. The composition of the product gas is determined by the simultaneous equilibrium between Equations (7) and (8 a).

Because soot formation should be suppressed, the Boudouard reaction (Eq. 10) and hydrocarbon decomposition (Eq. 12 and, especially, 12 a) are essential for an assessment of the reaction system.

Rich-Gas Process. When naphtha is reformed catalytically with steam in a shaft reactor to yield gases with a high methane content, the endothermic gasification reactions (Eqs. 8 and 9) must be considered as starting reactions, whose products are then transformed in an exothermic methanation reaction described by Equation (8). The final condition of the reforming process is determined by Equations (7) and (8 a).

Oil Gasification. In oil gasification with oxygen and steam, partial combustion of hydrocarbons (Eq. 4), as well as steam and carbon dioxide gasification of carbon (Eqs. 8 and 11), must be considered to proceed more or less simultaneously. Product gas composition is determined by the final state of the simultaneous equilibrium among the reactions described in Equations (7), (8 a), and (10).

Coal Gasification. The first step in a coal gasification reaction (e.g., with oxygen and steam in countercurrent mode of operation) is exothermic combustion of carbon to carbon dioxide, according to Equations (1) and (2). The carbon dioxide formed then reacts with hot carbon to yield carbon monoxide in an endothermic reaction (Eq. 6). This in turn reacts with steam to produce either hydrogen and carbon dioxide (according to Eq. 7) or methane and carbon dioxide (by the reverse of Eq. 11 a). The latter occurs particularly at increased gasification pressure. Carbon monoxide and hydrogen are also produced by direct endothermic carbon gasification with steam (Eq. 6). In entrained-flow gasification processes, the reaction sequence described is mostly overlapping. The mode of reaction essentially determines the temperature profile in a gas producer.

The composition of gasification gas is determined by a more or less accurate adjustment of the simultaneous equilibrium among the shift conversion reaction (Eq. 7), the methane reforming reaction (Eq. 8 a), and the Boudouard reaction (Eq. 10).

1.4. Characteristics of the Basic Processes

In most cases, the aim is to produce gases with high hydrogen and carbon monoxide content. This applies to all synthesis gases and also to town gas. Depending on the particular requirements, the carbon monoxide content may be reduced with steam to yield hydrogen and carbon dioxide. To produce such gases from various solid, liquid, and gaseous fuels, heat must be supplied to support the endothermic reactions. Thus, different processes can be classified according to the type of heat supply.

On the other hand, processes for producing gases with high methane content, such as rich gas and SNG, in principle require no external heat supply because methane formation is exothermic. Therefore, the process characteristics of this group are different.

Trends in the past decades have shifted from processes operated under atmospheric conditions to those operated at elevated pressure. This has resulted in economic advantages because the subsequent chemical syntheses [ammonia, methanol, oxo (→ Oxo Synthesis) and Fischer –Tropsch synthesis (→ Coal Liquefaction)] operate at more or less elevated pressure, which removes the cost of compressing the high-volume synthesis gas. Moreover, plants operating under pressure can be designed for higher capacity due to their smaller gas volume, which again means savings in capital costs.

An essential criterion is whether catalysts are used. With catalysts, a better approximation to reaction equilibria is attained and undesired byproducts are mostly avoided. However, catalysts can thus far be used successfully only for gaseous feeds and for distillate liquid feeds.

Cyclic Processes. Cyclic processes use heat carriers consisting of refractory brick lining (in

regenerators, air heaters, etc.) or beds of ceramic material, which may be appropriately impregnated to impart catalytic properties to them. Regenerative heating is provided by hot flue gases from the combustion of liquid or gaseous fuels. During gasification, the heat carrier transfers its heat to the raw material to be converted. The process is suitable for liquid and gaseous feedstocks. Any carbon black deposited during the reforming period can be burned off after the system is switched back to heating. The process is not suitable for operation at elevated pressure.

Processes using circulating heat carriers are similar to cyclic gasification except for being continuous processes circulating the heat carrier in a closed loop. This carrier is heated by hot flue gases and then fed to a reaction section in which its heat is used for gasification. In addition to sensible heat, some heat carriers used in the past also produced heat through reaction with gas components (producing $CaCO_3$ from burned lime and CO_2). Any carbon formed in the process can be burned off in the heating zone. The process is generally suitable for gaseous, liquid, and solid fuels. The circulating heat carrier may consist of granular catalytic or noncatalytic solids, or of liquids (such as slag baths) and circulating gas. Although system design does not altogether exclude elevated operating pressure, the necessary design and operating conditions would be difficult to meet.

Autothermal Processes. Autothermal processes produce the heat required for gasification through partial combustion of the fuel to be converted in the reactor. Oxygen or air — if nitrogen in the air is not a ballast in the product gas — is added for this purpose. The process may operate with or without catalysts. If catalysts are used, the temperature can be kept lower because a closer approach to equilibrium is ensured. However, the catalytic process cannot be used to gasify heavy and residual oils because most of these oils contain ash particles that contaminate the catalyst. Also, because of the ash content, catalysts for coal gasification are not applied, so far. Either the catalyst would have to be very cheap so that it could be disposed of along with the ash, or it would have to be recovered by a very complex procedure.

Processes applying baths of molten slag, iron, or salts as heat carriers and reaction promoters have been used and are still being developed. A characteristic of autothermal processes is that the oxygen added to generate heat is chemically bound in the product gas, so the ratio of hydrogen to carbon monoxide in the product is lower than in other processes. This type of process is applied to solid, liquid, and gaseous fuels.

Processes Involving Externally Heated Walls. Processes using externally heated walls include tubular reforming, which is used widely today. To keep the tube stresses resulting from elevated pressure and temperature to a minimum, all tubular reformers employ a catalyst filling in the tubes, which allows lower reaction temperature.

Modern materials permit tubes to be designed for wall temperatures of ca. 900 °C (in special cases even 1000 °C at atmospheric pressure) and pressures up to 4.0 MPa. All gaseous hydrocarbons (with low unsaturated hydrocarbon content) and distillate liquid fuels are suitable feedstocks. When liquid hydrocarbons are used, demands on the catalysts are extremely high. Virtually ash-free fuels are used almost exclusively to heat the tubes because ash constituents (salts, metals) would damage tube walls.

Reactors with externally heated walls are also used in gas production from solid feedstocks. This process technology offers the opportunity to employ nonfossil energy (heat from nuclear reactors, solar energy) for gasification.

Rich-Gas Processes. Because no external heat supply is required for rich-gas processes, the equipment and process loops can be chosen freely. In most systems, a catalyst is applied because methane formation is favored by lower temperature. Apart from the unfavorable equilibrium position, the risk of carbon deposits resulting from the Boudouard reaction is higher at increased temperature, and other byproducts are formed as well. All the processes operate at elevated pressure because this promotes methane formation.

Because catalysts are highly sensitive with respect to attrition, reactors are normally of the fixed- rather than the fluidized- or entrained-bed type. Raw materials must be virtually free of all

substances that may poison catalysts, particularly sulfur compounds.

1.5. Product Gas Treatment

Each gasification plant requires gas treatment facilities to purify product gases and also, in many cases, to condition them. Whereas the gas purification system eliminates the components that would affect downstream processing or utilization of these gases, the purpose of a conditioning system is to adjust gas components to the appropriate ratio. The ratio of hydrogen to carbon monoxide, especially, must be matched to the requirements of downstream synthesis or reduction units and other gas consumers.

The task of gas purification and conditioning is most complex downstream of plants gasifying solid fuels. Capital investment in these purification units can be much higher than that required for the gasification plant itself. Treatment of gases produced through gasification of high molecular mass liquid hydrocarbons (heavy oils, vacuum residues) is also rather expensive. Generally, the smaller the molecules from which a gas is produced, the lower is the capital investment required in treatment facilities. The costs of gas purification are also strongly dependent on the amount and type of impurities in the feedstock, particularly its content of sulfur and trace elements.

Whereas most catalytic gasification processes have some purification facilities (removing sulfur, lead, chlorine) upstream of the gasification stage, the impurities in noncatalytic processes should be removed only from the product gas.

Impurities in the Gasification Gas. Depending on the type and composition of feedstock and the type of gasification process used, a gas purification plant must handle the following impurities:

- Dust (coal gasification)
- Carbonization products, tar, gas liquor (coal gasification)
- Carbon (Heavy-oil gasification)
- Oxygen (coal gasification, oil gasification)
- Cyanic compounds (coal gasification, oil gasification)
- Nitrogen oxides (coal gasification, oil gasification)
- Carbon dioxide (all gasification processes)
- Hydrogen sulfide, carbonyl sulfide, organic sulfur
- compounds (all noncatalytic gasification processes)
- Ammonia (all gasification processes)

Other gas components, even if they occur only in trace amounts, require specific measures to prevent long-range damage or malfunction of the plant. This is particularly true for the gasification of coal and heavy oils. Such components may include volatile metal compounds and high molecular mass organic compounds.

1.5.1. Purification Processes

Because of the large number of impurities, along with their widely varying content and combinations, a variety of gas purification processes are available to meet the requirements of downstream processing (synthesis, in particular) and of industrial and municipal consumers (town gas). *Ammonia synthesis*, for instance, tolerates only ca. 5 ppm (mL/m^3) of oxygen compounds (e.g., O_2, CO, CO_2, and H_2O), and the sulfur content must be < 1 ppm (mL/m^3).

Methanol synthesis, on the other hand, requires a sulfur content of < 0.1 ppm (mL/ m^3) and the stoichiometric ratio $(c_{H_2} - c_{CO_2})/(c_{CO} + c_{CO_2})$ must be adjusted to ca. 2 (see Section 7.1.2). To achieve this ratio, the gas must contain a certain amount of carbon monoxide — a factor that influences the selection of gasification and purification processes and also raises the question of whether an additional process stage is required to convert carbon monoxide into hydrogen and carbon dioxide. Carbon dioxide need not be removed completely so the general plant design can be simplified considerably.

Reduction gases for direct reduction of iron ore may contain sulfur on the order of 7 ppm (mL/m^3), but the content of water and carbon dioxide should not exceed 5 vol %.

If several gas purification plants are combined for optimum effect, perhaps including gas conditioning facilities as well, possible interaction should be checked carefully. Interactions could occur because of solvents contained in the

gas, depending on their vapor pressure, different operating behavior, etc. If fuel gas is produced for a combined power cycle (see Section 7.3), the gas purification plant must meet the load change requirements of such plants.

Gas purification processes may be classified as follows:

Adsorption. Adsorption describes the retention of impurities by solids, either through physical deposition or through chemical reaction (chemisorption) (→ Adsorption , see also Section 5.5). Whenever solids have to be reused (e.g., for economic reasons), batchwise operation is necessary because the laden solids must be regenerated.

Sulfur compounds are eliminated by using beds of iron hydroxide and zinc oxide (especially for desulfurizing gaseous and liquid feedstocks for catalytic gasification). Activated carbon is favored in special cases for cleaning gases containing high molecular mass organic sulfur compounds.

Molecular sieves (→ Adsorption; → Zeolites) have been developed for selective removal of particular gases. They can be used not only for carbon dioxide, sulfur compounds, and steam, but also for diatomic gases.

Gas purification systems based on the adsorption (and chemisorption) principle are preferred when small quantities of impurities must be eliminated or small gas throughputs must be purified.

Absorption. A general distinction is made between physical and chemical absorption processes. Physical processes (→ Absorption, Chap. 1.4 , see also Section 5.4) are particularly suitable for high pressure, high impurity content, and large gas throughput. The processes available differ in solvents used, mode of plant operation, operating temperature, method of energy recovery, and potential for recovering several components more or less separately. The selection of appropriate solvents is determined to a large extent by their specific solubility coefficients for the desired gases and by their selectivity.

Chemical absorption systems (→ Absorption, Chap. 1.5) can be used at elevated or atmospheric pressure. They are particularly suitable whenever the absolute quantity of impurities to be removed is small. Conventional processes differ mainly in the degree of purity that can be achieved and the amount of energy (normally steam) required for regeneration. Numerous processes also use some combination of physical and chemical absorption principles.

Special Wash Processes. Special applications include the removal of solids entrained with gases in the form of dust or carbon black, dust-laden tar, and high molecular mass or unsaturated hydrocarbons that tend to form gums.

1.5.2. Conditioning

For nearly all applications, gasification gases not only must be purified but also conditioned to obtain the optimum proportions of desirable gas components (Sections 5.1, 5.2, 5.3).

Carbon Monoxide Shift Conversion. Prominent among gas conditioning processes is catalytic carbon monoxide shift conversion, which is based on water gas equilibrium (Eq. 7). By this process, the hydrogen content of a gas can be increased as desired at the expense of its carbon monoxide content. This is important not only for ammonia synthesis but also for town and grid gas production. The process permits the gas to be adjusted to the standard density and Wobbe index, and also enables nontoxic, low-carbon monoxide town gas to be produced, in conformity with current regulations.

Carbon monoxide shift conversion requires the addition of steam, which can be done in one of several ways. Steam at the appropriate pressure may be added directly to the gas to be converted. If steam is not available in sufficient quantities and under economically justifiable conditions, a so-called saturator cooler loop is often used. With this arrangement, gas entering the conversion section is humidified by circulating hot water, and unreacted steam in the gas leaving this stage is recondensed and recycled to the saturator. A distinction is also made between high- and low-temperature conversion, the latter being provided downstream of the former to reduce the residual carbon monoxide content of the gas to a minimum (e.g., for ammonia synthesis). Shift conversion catalysts for sulfur-free gases are based on iron (high temperature

shift) or copper (low temperature shift). They are supplied as oxides and reduced during operation. For gases containing sulfur compounds the shift catalysts are based on cobalt and molybdenum. They are active only as sulfides.

Methanation. Another gas conditioning method is methanation, the conversion of carbon monoxide, carbon dioxide, and hydrogen to methane according to Equations (8 a) and (9). A methanation stage is included in many ammonia synthesis plants to ensure a high degree of purity of the synthesis gas. Similarly, a methanation step is indispensable if a high-methane gas for SNG production is to be obtained.

Other Processes. The following processes may also be regarded as gas conditioning.

If the calorific value of town gas, grid gas, or SNG is insufficient, the gasification gas may be carbureted by adding C_3 and C_4 hydrocarbons or, less frequently, small quantities of high molecular mass hydrocarbons. On the other hand, too high a calorific value can be reduced by adding nitrogen, air, or oxygen.

For certain syntheses, gases must be dried. Drying is also necessary in pipelines, to protect the piping from corrosion where a risk of water condensation in the presence of carbon dioxide exists. In addition, the formation of gas hydrates is avoided.

Unlike town gas produced in the past from coke oven batteries, the town gas obtained today through gasification no longer contains any chemical compounds that produce a manifest odor. Therefore, such gases are now odorized artificially so that leaks occurring in the piping or at the consumer's facilities can be detected easily.

To recover particular components from a gas stream (e.g., H_2 from purge gas), pressure-swing adsorption (PSA) (→ Adsorption) or membrane processes (→ Membranes and Membrane Separation Processes) can be used. The PSA principle is based on the fact that the adsorption capacity of molecular sieves (→ Zeolites) differs for different gases. Generally, heavier or polar gas components are adsorbed preferentially. When a gas mixture is passed over a molecular sieve bed, the component least amenable to adsorption (e.g., H_2) remains in the gas whereas other components are adsorbed.

Gas separation by membranes is based on the differences in permeation coefficients of different gas components. Permeation denotes the sequence of absorption (solution) of the component in the membrane material, diffusion through the membrane, and desorption. The permeation rate of a species increases with its solubility and its diffusion coefficient in the membrane material. Membranes may consist of ceramic or metallic materials, organic liquids, or polymers.

Both processes, PSA and membrane separation, can be used to advantage for gases at elevated pressure.

To remove traces of higher hydrocarbons (e.g., compressor lubricants) from gases, beds of activated carbon are used. For recovery of low-boiling compounds, as well as purification from traces of higher boiling compounds, cryogenic processes (→ Cryogenic Technology) can be applied. These employ primarily liquid methane or nitrogen to absorb higher boiling gases such as carbon monoxide.

1.5.3. Byproducts

Some gasification processes yield byproducts along with the desired gas (see also Chap. 6). A comparison of different gasification processes should, therefore, always consider such byproducts and assess their importance. Environmental protection, too, plays an important role because it imposes stringent conditions on pollutant discharge.

Many gasification plant feedstocks contain sulfur, and sulfur often constitutes the main byproduct. Whether this is best recovered in the form of elemental sulfur or sulfuric acid is worth considering.

Other coal gasification processes have coke as a byproduct.

Gasification involving coal carbonization processes can produce a large number of byproducts such as tar, oil, gasoline, phenols, cresols, ammonia, and organic acids. Certain liquid byproducts may even contain solids whose elimination would result in additional costs. Because of this, processes have been developed to recycle certain liquid fractions to the gasification plant if their market value is low.

Heavy-oil gasification plants yield carbon as a byproduct. Attempts to use it for special industrial applications have been successful, but demand for the specific qualities of carbon is limited. Therefore, processes are being developed to recycle most of this carbon to the gasification stage. These and processes where carbon is burnt in conventional power stations at little extra cost are of major interest.

Gas liquor is a product of almost all gasification processes. Depending on its composition and on plant requirements, this gas liquor can either be treated for use as boiler feed water or cooling water, or be discharged to receiving water via chemical or biological effluent treatment plants.

2. Steam Reforming of Natural Gas and Other Hydrocarbons

In the steam reforming process hydrocarbons are catalytically converted by reaction with steam into hydrogen and carbon oxides. This is the most common method for producing hydrogen or hydrogen: carbon oxide mixtures in the manufacture of important basic chemicals (e.g., ammonia and methanol), oil refining, and in many other industrial applications (e.g., iron ore reduction, hydrogenation of fats, production of oxo alcohols).

Nowadyas natural gas predominates by far as a feedstock over other hydrocarbons (e.g., naphtha, LPG, refinery gases) or coke oven gas which are used only under special circumstances.

The catalytic steam reforming process in tubular furnaces was invented in 1926 – 1928 by BASF [7]. This process was applied in the United States for the first time in the early 1930s at two commercial plants: (1) to produce hydrogen from natural gas for hydrogenation purposes and (2) to synthesize ammonia. The process was conducted under low pressure (0.4 – 1 MPa) and at temperatures close to 800 °C until the early 1950s; pressures up to 4 MPa and temperatures up to 950 °C are used today.

A special type of steam reforming which has been in use even earlier than tubular steam reforming is *autothermal reforming*, also called *catalytic partial oxidation*. This process differs from catalytic steam reforming in that the required reaction heat is not supplied from outside (furnace) but by internal partial combustion of the feedstock with oxygen or air, admixed to the process feed. As autothermal reforming is carried out in refractory-lined vessels (cold shell), higher pressures can be applied than in tubular steam reforming. Outlet temperatures up to 1000 °C are usual. Due to the additional expenditure for oxygen supply and safe process control this technology was of minor general importance in the past. Of common use, however, is the process modification with air as oxidant in ammonia synthesis. More recently, the oxygen based gasification has been introduced into methanol synthesis. "Combined reforming", a combination of tubular and autothermal reforming, is recognized as the most efficient syngas technology for large scale methanol plants at the moment.

A comprehensive overview of recent developments in steam reforming technology is given in [8].

Whereas in former years steam reformers have been built nearly exclusively at locations where there was requirement for hydrogen or synthesis gas and products derived therefrom, a big change has occurred since the 1970s, in that particularly world-scale production plants for ammonia and methanol have been built at locations, where natural gas is available in abundance (e.g., Trinidad, Borneo, Cape Horn).

Total hydrogen production by catalytic reforming currently (ca. 2000) amounts to over 400×10^9 m^3/a worldwide. Its uses can be broken down approximately as follows: 60 % for ammonia production, 10 % for methanol production, 25 % for petrochemical processes (hydrotreating, hydrodesulfurization, hydrocracking), and 5 % for other industrial purposes. The cost of commercial production is about $ 0.10 per cubic meter of hydrogen. The catalytic steam reforming process is especially low in emissions. Only the off-gas from the steam reformer contains, apart from carbon dioxide, a certain amount of NO_x and, depending on the feedstock, sulfur dioxide.

2.1. Feedstocks

Natural Gas. Natural gases (→ Natural Gas) are used as gasification feedstocks, either directly or after appropriate pretreatment. Table 5

gives examples of pretreated natural gases and other hydrocarbon feedstocks. High-boiling hydrocarbons are largely eliminated before transportation to prevent condensation in the distribution system.

Particular attention must be paid to sulfur compounds in natural gas. A gas suitable for catalytic reforming has to be virtually free of these compounds as sulfur is a strong poison to the employed catalysts. High percentages of nitrogen are undesirable as well, except in ammonia synthesis gas. For hydrogen – carbon monoxide gases, nitrogen must be removed in a complex operation. A certain percentage of carbon dioxide may be tolerated and even be beneficial in methanol production.

The condensation fractions recovered from casinghead gases (see Table 5) extend into the naphtha range and contain higher hydrocarbons that may create problems in catalytic reforming. These fractions are handled similar to naphtha.

Reevaporated liquefied natural gas (LNG) is free of all accompanying components such as carbon dioxide, steam, sulfur compounds, and C_{5+} hydrocarbons, which must be removed for process reasons prior to liquefaction. It does not contain any gas with a lower boiling point than methane, such as nitrogen or noble gases (helium). However, when obtained from the public grid, LNG may contain sulfur compounds (used as odorants; e.g., tetrahydrothiophene) and nitrogen (from calorific value – density conditioning).

Other Gases (see Table 6). Gases of different qualities are derived from refineries, coking plants, the chemical industry, steelworks, etc. They are suitable not only as fuel gases but, increasingly, as gasification feedstocks or as raw materials for the chemical industry. As a typical example, hydrogen used in a refinery can be produced by the conversion of refinery gases or butane.

purge gases) from ammonia and methanol synthesis or olefin production are also used for gas production. Unsaturated hydrocarbons in the residual gases are usually saturated by hydrogenation before they are catalytically gasified with steam. The top gas from some processes for direct reduction of iron ore is upgraded by adding fresh natural gas and used for gas production. Coke oven gas, which was formerly used mainly as town gas, is utilized today for ammonia production or the reduction of iron ore.

Naphtha. At the beginning of the 1960s, light naphtha was available in large quantities for the production of town gas, ammonia, and methanol. Since the 1973 oil crisis, it has been used almost exclusively as a raw material for the production of chemicals (especially ethylene). Exceptions are town gas and synthesis gas production in isolated areas where no natural gas is available.

A distinction must be made between straight-run virgin naphtha as obtained directly from crude oil distillation and naphtha cuts from the production facilities of a refinery, for example, from a reforming unit (high-aromatic naphtha).

Naphthas differ according to geographical origin of the crude. The main criteria for assessing the suitability of a naphtha as a raw material for gas production are its boiling range (low boilers can be converted more easily); carbon: hydrogen ratio; aromatic, olefin, and naphthene contents; sulfur content; and content of metals or other substances (e.g., lead, chlorine, which will poison the catalyst). Table 7 shows the principal characteristics of various naphthas.

Generally, low-boiling naphthas rich in alkanes are preferred for catalytic gasification because they are easier to convert and the catalyst has a longer service life. In individual cases, naphtha with a boiling end point up to 220 °C, mixtures of naphtha and kerosene, or kerosene itself may be considered as raw materials.

Ammonia and Methanol. Ammonia and methanol are occasionally used as feedstocks for hydrogen production (in small units and for peak shaving gas).

2.2. Natural Gas and Other Gaseous Hydrocarbons

In the 1920s BASF developed a catalytic process for endothermic conversion of gaseous hydrocarbons with steam in externally heated tubes, using nickel as a catalyst. Exchanges of experience with Standard Oil (New Jersey) and ICI in the 1930s led — particularly in the United States and England — to the first commercial application of this process in the production of hydro-

gen for hydrogenation and ammonia synthesis. These plants operated at atmospheric pressure. New reformer tube materials, especially the development of centrifugally cast tubes, permitted higher pressure in the gas production section, which in turn improved plant efficiency considerably.

2.2.1. Principles

Catalytic conversion of hydrocarbons with steam to produce gases with high hydrogen and carbon monoxide content, according to the reactions (8) and (8 a) — and always accompanied by the shift conversion (Eq. 7) (see Section 1.3) — is known as steam reforming. This conversion is highly endothermic. It occurs in a number of parallel, externally heated tubes (reformer tubes) filled with a nickel catalyst.

After being preheated in heat exchangers or fired heaters to ca. 500 °C, the steam – hydrocarbon mixture is heated further over nickel catalyst in the tubes to the desired end temperature of normally 800 – 900 °C. Higher hydrocarbons (Eq. 8) are completely converted to carbon monoxide and hydrogen, methane only partially — corresponding to the reaction conditions. The composition of the reformed gas at the reformer outlet reflects the equilibria of Equations (8 a) and (7). For specified conditions (pressure, reformed gas temperature, steam – hydrocarbon ratio), the composition of the reformed gas can, therefore, be calculated from component balances and equilibrium conversion rates. The steam: hydrocarbon ratio is an essential parameter in the steam reforming reaction and must not be lowered arbitrarily, because low ratios lead to carbon deposits on or in the catalyst. Figure 2 shows the influence of pressure and temperature on the composition of the reformed gas for a defined steam: methane ratio in a methane reforming unit.

Figure 2. Equilibrium composition for methane reforming at 500 – 1000 °C and pressures (in the direction of the arrows) of 0.1, 0.5, 1, 1.5, 2, 2.5, 3, 3.5, 4 MPa. Molar steam: methane ratio 3.333 corresponding to 5 kg H_2O per kilogram of carbon

Kinetics. The kinetics of catalytic steam reforming of methane are summarized in [9, 10] and [11]. Many authors observe that the shift conversion reaction described by Equation (7) proceeds very fast so that the gas composition may be assumed to be in equilibrium at every point in the reformer tube — a proposition that is not true for methane conversion which approaches to equilibrium only towards the outlet of the tubes. Sulfur in the gas has no decisive influence on the shift conversion, but can decrease the reaction rate of the hydrocarbon conversion dramatically, especially at the inlet side of the tube.

Methane reforming can be described as a first-order reaction, irrespective of operating pressure. At low temperature, the molecular diffusion rate is much higher than the reaction velocity so that, theoretically, the catalyst activity can be fully utilized. If the temperature is high, the conversion rate is determined by pore diffusion, and catalyst efficiency is reduced. Hence, large-surface catalysts offer an advantage with regard to catalytic activity. For further details of reaction mechanism and kinetics, see [12] and [13].

Carbon Deposition. Carbon deposition is a frequently experienced phenomenon with steam reforming. Though generally various reactions may cause solid carbon formation from carbon compounds containing gaseous phases [e.g., Boudouard reaction ($2\,CO \rightleftharpoons C + CO_2$), hydrocarbon decomposition ($C_nH_m \rightleftharpoons n\,C + m/2\,H_2$), the heterogeneous water gas reaction ($CO + H_2 \rightleftharpoons C + H_2O$)], hydrocarbon decomposition is practically the exclusive cause for carbon formation in the course of reactions in the steam reforming process. Therefore carbon deposition is observed mainly in the first half of the reformer tubes where hydrocarbon concentrations are still high and the approach to equilibrium low.

Investigations have shown [14] that the thermodynamic limits of carbon formation (graphite) do not apply below 700 °C because there the relevant reactions are dominated by kinetics. So the carbon-free area may increase, depending on catalyst properties. Figures for a uranium – nickel – α-alumina catalyst are given in [15] and for a number of other catalysts in [13].

Figures 3 and 4 show experimental "equilibrium constants" for the Boudouard reaction and methane decomposition measured by various authors, as well as calculated figures for thermodynamic equilibrium according to [16]. Figure 4 also depicts the "working line" for methane steam reforming according to [17], by applying two catalysts with different activities. Points on the curves indicate the location of the measuring point as a proportion of tube length (viewed from the gas inlet).

In steam reforming of natural gas, the temperature at the catalyst inlet is such that carbon might theoretically be deposited. This does not occur, however, below ca. 650 °C, but only at higher temperature when an inactive catalyst fails to decompose sufficient methane. Generally, the formation of carbon deposits is not inevitable even at operating temperatures where it might be expected.

Figures 3 and 4 also illustrate the more favorable initial situation and possible further reforming of a naphtha-based rich gas with added carbon dioxide (to obtain high-CO gases) if catalyst activity remains unimpaired (line (c) in Fig.

3 or line (a) in Fig. 4) or if no further methane conversion occurs (line (b) in Figs. 3 and 4).

2.2.2. Catalysts, Catalyst Poisons, Desulfurization

Steam reforming is generally carried out in the presence of nickel catalysts. These catalysts are usually in the form of thick-walled Raschig rings, with 16-mm diameter and height and a 6 – 8-mm hole in the middle. However, especially in modern steam reformers with high heat flux, catalysts with high geometric surface (HGS-type) are preferred. As already mentioned in Section 2.2.1, the access to the inner surface of catalysts continuously decreases with increasing temperature due to diffusion limitation. This is compensated by introducing catalysts with a higher surface to volume ratio. Typical shapes of this type of catalysts are spoked wheels, gear wheels, or rings with several holes. These catalysts are additionally advantageous with regard to their low pressure drop.

A general distinction is made between impregnated and precipitated catalysts. The latter are the more traditional types which are produced by coprecipitation of all constituents. *Precipitated catalysts* have a Ni-surface which is by one order of magnitude higher than that of impregnated catalysts and for this reason have an excellent activity already at moderate temperatures. But they are more prone to sintering at higher temperatures and do not have the mechanical strength of supported catalysts.

Impregnated catalysts are manufactured by separately impregnating a support with nickel as the active constituent. The main advantage of this type of catalyst is that the support can be calcined at high temperatures before impregnation, resulting in predetermined excellent mechanical properties which are important especially at high temperature application. As the conditions of steam reforming have generally become more severe, impregnated catalysts predominate by far at present. Frequently used support materials are alumina (the α-modification is preferred today), magnesium oxide, or spinel type substances (e.g., magnesium aluminum oxide). In some cases, catalysts are stabilized by addition of a hydraulic binder (calcium aluminum oxide). Crushing strength is decreased by the hydration of magnesium oxide at low temperature (< 500 °C) and by changes from the γ to

the α-modifications of alumina above 500 °C. A silicon dioxide content of < 0.3 wt % in the catalyst is essential, because silicon dioxide becomes volatile in the presence of steam and may foul the downstream heat exchangers through which the reformed gas flows.

Nickel is at first present in the form of nickel oxide; after the system has been heated, it is reduced in the reformer tube by hydrogen formed when natural gas is added to steam. Some catalysts require a special method of reduction for which a definite steam: hydrogen ratio must be maintained (see Fig. 5), according to [12] and [13].

Figure 5. Reduction conditions for nickel oxide

Catalyst Poisons and Desulfurization. Catalytic activity is affected seriously even by very low concentrations of catalyst poisons in gases to be reformed. Such catalyst poisons are sulfur, arsenic, copper, vanadium, lead, and chlorine or halogens in general. Sulfur, found in practically all hydrocarbon feedstocks, in particular lowers catalyst activity [18].

Earlier desulfurization systems used impregnated activated carbon as adsorbent and operated at ambient temperature. However, because their efficiency differs according to the particular sulfur compounds in the gas and because the requirement with regard to the residual sulfur content has increased, zinc oxide desulfurization systems operating at 350 – 400 °C are generally preferred today. Iron-based adsorbents are used in only a few cases where special conditions (i.e., low operating temperature, possibility of regeneration, sulfur composition) prevail.

Zinc oxide reactors are very reliable in absorbing hydrogen sulfide and, with limitations, sulfur compounds such as carbonyl sulfide and mercaptans. To achieve optimum desulfurization conditions, certain space velocities and effective flow rates must be ensured. Sulfur pickup ranges from 15 to > 30 %, that is almost complete conversion of zinc oxide to zinc sulfide is possible.

Organic sulfur compounds such as mercaptans and thiophenes require hydrogenation over cobalt – molybdenum or nickel – molybdenum catalysts. These catalysts are often arranged in a separate vessel. Hydrogen or hydrogen containing gas are added to the process feedstock at temperatures of ca. 350 – 380 °C. The organic sulfur compounds are converted to hydrogen sulfide and the corresponding saturated hydrocarbons. Hydrogen sulfide produced in the hydrogenation stage is then absorbed by zinc oxide. The hydrogenation reactor can be used simultaneously to hydrogenate unsaturated hydrocarbons in the raw gas. This reaction is strongly exothermic. Because the temperature range for the hydrogenation stage is limited to 250 – 400 °C, unsaturated hydrocarbon content is limited as well. Ammonia, carbon monoxide, or carbon dioxide impurities in hydrogen affect desulfurization and can lead to undesirable side reactions such as methanation [12]. An economic solution particularly for natural gases with low sulfur content is the combination of hydrogenation and zinc oxide absorption. This means that both catalysts can be combined in one bed in the same reactor. Residual sulfur content is normally < 0.2 mg/m^3 [19].

2.2.3. Tubular Reformers

Tubular reformers are mostly top- and wall-fired box-type units, apart from older types or special designs (Fig. 6). Whereas in *wall-fired reformers*, rows of reformer tubes are heated mainly by the radiant side wall, *top-* or *bottom-fired reformers* provide most of the heat through radiation of the burner flame and the hot flue gases. Top-fired reformers may, therefore, have several parallel rows of tubes, whereas wall-fired reformers can have only one row. Wall-fired reformers with a large number of tubes consist of several units adjacent to one another; waste heat from the flue gases is recovered in a common system. Modern reformers in large plants that produce ammonia and methanol synthesis gas from natural gas contain hundreds of tubes arranged in rows.

Figure 6. Reformer types
A) Top-fired reformer; a) Inlet header(s); b) Pigtail; c) Burner; d) Catalyst-filled reformer tube; e) Flue-gas collector; f) Refractory lined outlet manifold; g) Outlet pigtail; h) Outlet manifold
B) Wall-fired reformers; a) Inlet header; b) Flue-gas duct; c) Wall burners; d) Outlet manifold; e) Terraced wall; f) Burner

Firebox. The reformer box consists of several layers of refractory insulation and insulating mats with an exterior metal skin. The hot face refractory must be resistant to temperatures > 1200 °C; the temperature is reduced to ca. 75 °C on the outside of the metal skin.

Burner geometry, flame length and diameter, tube-to-tube and row-to-row spacing, fired tube length, and distance from the flame to the reformer wall determine the homogeneity of heat transfer to the tubes. Modern computers are capable of linking up this reformer geometry with heat-transfer processes inside the reformer tubes (radial heat conductivity) to derive complex equation systems from which heat transfer at all points of the firebox can be calculated (see Fig. 7). These equations yield local temperature profiles for flame – flue gas (g – f), reformer wall (d), tube wall (b), (c), reformed gas (a) or catalyst, and local heat flux (e). These figures form the design basis for the reformer. If the tube wall temperature and local heat flux are known, and heating and cooling rates are estimated, the wall thickness of the reformer tubes can be calculated.

One important factor is spacing between the reformer tubes, referred to as tube pitch. In calculating tube pitch, irregularities in heat flux around the tube must be considered [20].

Burners and Firing Systems. Top-fired reformers use turbulent open-jet burners with forced air supply. Appropriate selection of parameters such as jet diameter, fuel and air supply rates, and burner geometry produces a relatively short, stable flame ca. 2 – 2.5 m in length; the reformer tubes, therefore, receive their heat to a considerable degree from flue gas radiation. Accurate calculation of heat transfer requires a knowledge of flue gas backflow and flame emission behavior.

Figure 7. Approximate temperature profiles across a reformer
a) Reformed gas (average over tube cross section); b) Tube wall inside; c) Tube wall outside; d) Heater wall; e) Local heat flux; f) Flue gas; g) Flame

Flue gases are discharged via ducts inside the firebox and cooled to ca. 200 °C in heat exchangers, which are used to preheat the gaseous feedstock, generate steam, etc.

Wall-fired reformers employ other burner designs or flame shapes, such as resist burner cups

into which the fuel is burned or flames burning parallel to the side wall.

Reformer Tubes. Normally, the tubes have inside diameters of 75 – 125 mm, wall thicknesses of 10 – 20 mm, and fired lengths of 9 – 15 m, depending on reformer type (top- or wall-fired). The fixed tube support is usually located outside the firebox at the top or bottom; when heated, the tube expands longitudinally from this support. Counterweights or spring hangers often relieve the tubes of ca. 50 % of their dead weight.

Tube wall thickness is calculated on the basis of internal pressure and of 100 000-h creep-to-rupture strength; see [20]. More sophisticated calculations allowing for mechanical and thermal stresses, and in some cases even establishing a link between them, are being used increasingly [21, 22].

Table 8 summarizes tube materials currently preferred, along with their rupture strengths. Tubes are welded to the required overall length from centrifugally cast tube sections > 3 m in length. The calculated "sound wall thickness" must be increased by an allowance for fabrication tolerances.

The pressure drop inside a reformer tube depends on the gas flow rate and geometry of the catalyst; it is normally between 0.15 and 0.5 MPa.

Pressurized Convection Reformers. A major factor determining the size of reformer tubes is the pressure difference between the reformed gas and the nearly pressureless flue gas. Obviously, the wall thickness of the reformer tubes can be reduced if the pressure in the firebox is increased. This concept is now mature enough for application on an industrial scale [23]. Reformer tubes with a much larger diameter than usual can be employed; the catalyst is arranged in an annular space, and reformed gas is recycled internally by straight or helically coiled tubes (to increase internal heat exchange). Such reformers can be designed for hydrogen output up to 5000 m^3 (STP)/h; beyond this, the wall thickness of the pressure vessel makes the concept economically unattractive.

Higher output can be achieved by connecting several units in parallel. The pressurized combustion reformer requires little space and can, therefore, be prefabricated in modules. However, combustion air and off-gas from the PSA unit required for the firing system must be compressed to high pressure, whereas the flue gas pressure energy can be recovered only partly in expanders.

A promising route for the future might be to increase process pressures to a level at which compression of synthesis gas is no longer required [24].

Inlet Header and Outlet Manifold Systems. The preheated hydrocarbon: steam mixture (400 – 530 °C) is fed to the reformer tube rows via inlet headers with branches to each individual reformer tube. These inlet pigtails are designed to take up the expansion of the inlet header and of the tubes (if the fixed support is underneath the reformer), as well as their own expansion. Header and pigtails are made of carbon steel (or alloyed carbon steel). Flexible metal hoses are used instead of inlet pigtails only in special cases.

Hot reformed gases are discharged from below the catalyst supporting grid in the tubes to outlet manifolds. The outlet manifolds are made of centrifugally cast (see Table 8) or drawn material (Incoloy 800 H). Brick-lined manifolds are used as well; in this case, reformer tubes are mounted directly on the manifolds or connected by small-diameter straight tubes, or "flexitubes" [25]. Another design has manifolds installed in the bottom of the firebox; product gas is extracted through the reformer top by means of one or more risers.

On leaving the outlet manifold, the hot reformed gases are cooled in heat exchangers to generate steam or to preheat boiler feedwater, raw gas, etc. They are then fed to carbon monoxide shift conversion units or carbon dioxide scrubbers for further conditioning.

2.2.4. Production of Fuel Gas and Synthesis Gas

Operation of the reformer under defined reaction conditions, in conjunction with additional process steps, produces the desired gas composition for fuel gas or synthesis gas applications. The variety of possibilities is indicated in Table 9, which lists typical reaction parameters for tubular reforming.

Table 8. Creep-to-rupture strength (average for minimum values) σ_{Rmin} 100 000 for centrifugal castings, N/mm^2

Material designation (DIN 17 006)	Trade names	Temperature, °C

Reduction gas	desulfurization, tubular reforming, or top gas recycling upstream of tubular reforming	1.25 – 1.5 0.65	0.2 – 0.3 0.15 – 0.2	850 – 1000 900 – 1000

* PSA = pressure swing adsorption; HT = high temperature; LT = low temperature.

2.2.5. Special Reforming Processes

Reforming with Additional Carbon Dioxide. Reforming with additional carbon dioxide is used to produce gases with an increased carbon monoxide content. By recycling carbon dioxide from the reformer product gas, partially or totally, the hydrogen: carbon monoxide ratio can be adjusted in a range defined by the composition of the natural gas. By total carbon dioxide recycle the complete carbon content of the process feed is converted to carbon monoxide. In this case the shift conversion reaction (Eq. 7) is eliminated and the hydrocarbon conversion follows exclusively Equation (8). Product gases with particularly high content of carbon monoxide are obtained by adding carbon dioxide from an external source in addition to the carbon dioxide recycle to the reformer feed. This combined steam – carbon dioxide reforming entails a greater risk of carbon deposits, which must be countered by selecting appropriate reaction parameters and catalysts (see Section 2.3.3).

Whereas reduction gases having high hydrogen and carbon monoxide content are normally produced by methane reforming with only a slight amount of steam being added (< 1.5 mol of steam per mole of methane), the Midrex process in particular (direct reduction of iron oxide, → Iron, Chap. 2.6.1) relies heavily on combined steam: carbon dixoide reforming.

Midrex Reforming. In the Midrex process, iron ore reduction and the production of reduction gas are integrated. Natural gas is mixed with off-gas from iron reduction (cleaned and humid-

ified gas from the direct reduction furnace). The latter contains unreacted hydrogen and carbon monoxide in addition to steam and carbon dioxide produced by oxidation of carbon monoxide in the furnace. Typical for the process is a steam: carbon ratio (regarding the molar carbon content of only methane and higher hydrocarbons) of 0.65 and a carbon dioxide: carbon molar ratio (see above) of ca. 0.8. Pressure at the reformer outlet is ca. 0.2 MPa. Special catalysts (Midrex and others) ensure that gases can be reformed without carbon formation.

To this end, either catalysts of different activities must be arranged successively in the reformer tubes, or the activity of the catalyst must be adjusted by means of a controlled sulfur content so that it will be lower at the tube inlet than at the outlet. Reformed gas is conditioned preferably to a hydrogen: carbon monoxide molar ratio of ca. 1.6. Processes for the production of direct reduction gases are described in [26].

Steam Reforming with Addition of Air. In the past, town gas was produced with addition of process air to adjust gas density; examples are the Koppers natural gas reforming process and the Dr. Otto butane reforming process. However, with the conversion of fuel gas systems to natural gas, this technology has become less important. It is still used to make synthesis gas for ammonia production from low-boiling hydrocarbons up to the naphtha boiling range in small compact plants containing a combination of primary and secondary reformers (see below).

Lately, natural gas reforming with addition of air has been used temporarily to adjust gas density during the changeover period from town gas to natural gas until the conversion of gas appliances to natural gas is completed.

The standard technology for producing ammonia synthesis gas from low-boiling hydrocarbons is the two-stage reforming process. The first stage is catalytic steam reforming of hydrocarbons in a tubular reformer (*primary reformer*). Product gas from the primary reformer, which has a temperature of ca. 800 °C, is then reformed with air in an autothermal *secondary reformer* at an outlet temperature of ca. 1000 °C (Section 2.5).

Methane Reforming with Nuclear or Solar Energy. In high-temperature nuclear reactors, recycled helium is heated from 350 to 950 °C. For catalytic reforming, hot helium is circulated in indirectly heated heat exchangers in countercurrent to methane and steam flowing through the reformer tube, releasing its sensible heat and being cooled from 950 to 600 °C. The preferred reformer tube design has an inner helical tube through which reformed gas is discharged to heat the catalyst-filled tube; see [27, 28]. Such reactors, termed EVA reactors, have been tested in pilot plants since 1971 and are considered suitable for commercial reformed gas production. Energy is supplied to the heating helium in the core of a high-temperature nuclear reactor. In *CRS* (i.e., Central Receiver System) *solar plants*, this occurs in the receiver.

Reformed gas can be used to produce basic chemicals (H_2, NH_3, CH_3OH) or, in conjunction with methanation, as a heat-transfer system (ADAM – EVA Systems, see Section 5.3.4). No known commercial applications have yet been found.

2.3. Tubular Steam Reforming of Liquid Hydrocarbons

In the mid-1950s, ICI initiated widespread use of naphtha as feedstock for the steam reforming process. This was enabled by the development of special nickel catalysts in conjunction with a very efficient naphtha desulfurization. Initially, the ICI process was frequently used for town gas production. Due to the abundance of natural gas, naphtha reforming is meanwhile of minor importance. Only at some locations with no access to natural gas there is still some hydrogen and syngas production based on naphtha.

Principles. Direct reforming of naphtha is not generally different from natural gas reforming. The conversion follows Equation (8) in the same way as already described for the higher hydrocarbons contained in natural gas (see Section 2.2.1). Like natural gas reforming naphtha reforming is carried out in externally heated tubes over a nickel catalyst and yields, via a complex reaction mechanism, a gas mixture consisting of hydrogen, carbon monoxide, carbon dioxide, methane, and steam. The gas composition reflects the equilibria of Equations (8 a) and (7) at

outlet conditions. If less active or partially deactivated catalysts are used, the equilibrium concentration of methane (as per Eq. 8 a) is not attained, and the methane content of the reformed gas is higher than at equilibrium. Due to the higher carbon content in the process feed naphtha reforming results in a product gas with increased carbon monoxide (and dioxide) content compared to natural gas feed.

2.3.1. Commercial Processes

A mixture of desulfurized and evaporated naphtha with superheated steam (molar steam: carbon ratio 3: 1 or higher) is supplied to reformer tubes at 450 – 550 °C.

Catalyst. Due to the high carbon: hydrogen ratio in the feedstock naphtha direct reforming is characterized by an increased tendency of carbon formation. This is mainly caused by naphtha cracking and dehydrogenation reactions, especially on acidic centers of catalysts based on alumina which is the most frequently used support material. The breakthrough of naphtha reforming has been enabled by the development of alkalized catalysts. The acidic centers of the support are neutralized by adding potassium to suppress naphtha cracking. Moreover, the steam conversion of carbon once formed by naphtha cracking is strongly enhanced by the presence of potassium. However, alkali also delays complete reforming to carbon monoxide and hydrogen. Therefore, the portion of the reformer tube that is filled with potassium-laden catalyst is restricted to the minimum required for reliable naphtha conversion; the rest of the tube is filled with more active alkali-free catalyst.

Today, a controlled continual release of potassium is achieved by incorporating a special potassium compound ($KAlSiO_4$) in the catalyst, thereby reducing the potassium vapor pressure [12]. Alternatively, alkali-free catalysts mostly based on magnesium oxide are used.

Desulfurization. Naphtha generally contains organic sulfur compounds, and the sulfur content may be as high as several hundred parts per million. It must, therefore, undergo hydrogenating desulfurization with hydrogen at 350 – 400 °C. Cobalt – molybdenum catalysts or, if gases with a certain carbon oxide content are intended for hydrogenation, nickel – molybdenum catalysts are used. The sulfur converted to hydrogen sulfide is then adsorbed on zinc oxide, which has been used commercially as a hot desulfurization agent since the 1940s.

2.3.2. Fuel Gas and Synthesis Gas from Liquid Hydrocarbons

The description given in Section 2.2.4 and Table 9 applies analogously to the production of gas from naphtha. These plants are distinguished from those based on natural gas by the following features:

1) More complex desulfurization systems;
2) Use of a special catalyst in the tubular reformer and, in conjunction with this, a special start-up system;
3) Fewer reformer tubes per quantity of hydrogen and carbon monoxide produced at equal heat loads per unit area (natural gas requires considerably more reforming energy than hydrocarbons in the naphtha boiling range); and
4) Larger carbon dioxide washing systems (naphtha has a higher carbon content than methane).

Details of modern integrated *ammonia plants*, particularly the steam system, are described elsewhere (→ Ammonia) [9].

In *town gas production* by the ICI process, the reformed gas is produced with a heating value below that of town gas. The calorific value of the reformed gas must, therefore, be increased

1) By adding low-boiling hydrocarbons (e.g., LPG) and
2) By producing gases with a higher calorific value in special process stages for addition to the reformed gas. This has been achieved by means of a downstream gas recycle hydrogenator (GRH) or a parallel rich-gas stage based on naphtha (see Section 2.4), or by reacting reformed gas from the tubular reformer with additional naphtha and steam in a secondary reformer [29].

2.3.3. Special Processes

Steamless Carbon Dioxide Reforming. Feedstocks with high carbon: hydrogen ratios

(such as naphtha) and low steam: carbon ratio favor the production of synthesis gas with high carbon monoxide and low hydrogen content (as required, for instance, for the oxo synthesis). In practical applications, however, this system soon reaches the point at which carbon formation occurs, particularly at high pressure. This difficulty has until now been overcome by reforming the gases under established process conditions (i.e., CO_2 recycling with less steam than in regular steam reforming), washing out carbon dioxide, separating hydrogen and carbon monoxide in a cryogenic or PSA unit, and finally remixing them in the desired ratio. In this concept undesirable hydrogen surplus can often be used only to fire the reactor.

The hydrogen production can be minimized by converting hydrocarbons only with carbon dioxide according to the reactions

$$CH_4 + CO_2 \rightleftharpoons 2\,CO + 2\,H_2$$

or as example for higher hydrocarbons

$$C_3H_8 + 3\,CO_2 \rightarrow 6\,CO + 4\,H_2$$

This leads to hydrogen: carbon monoxide ratios of 1: 1 or even less.

Steamless carbon dioxide reforming requires still more sophisticated conditions and catalysts than naphtha direct reforming [30]. It has been realized in the Calcor C process that employs special catalysts and ambient or only slightly elevated pressure. This system recovers the necessary carbon dioxide from the reformed gas in a monoethanolamine (MEA) or diethanolamine (DEA) wash unit, recycles it to the reforming stage, and adds imported carbon dioxide as required [31].

Downstream of the reformer and carbon dioxide wash unit, raw gas from a C_3– C_4 feedstock, for example, will contain hydrogen and carbon monoxide at a ratio of ca. 0.65, with a methane content below 1 vol %. For higher carbon monoxide concentrations, ranging to > 99.5 vol %, carbon monoxide and hydrogen are separated in a PSA unit or cold box. Plants designed for 160 and 250 m^3 (STP) of carbon monoxide per hour have been constructed to date.

Higher Feedstocks. Catalytic reforming of hydrocarbons with a higher boiling range has often been investigated. In most cases, only short-term tests were made, which did not reach the stage of commercial application. The use of very high-boiling hydrocarbons is described in [32].

In other tests, naphtha, crude oil, and heavy residues have reportedly been converted to reformed gases with a hydrogen content of ca. 60 – 65 % without desulfurization or removal of heavy metals [33]. The alternative of noncatalytic conversion of high boiling hydrocarbons or even residues and the high availability of natural gas have slowed down the interest in these feedstocks at present.

2.4. Prereforming

Prereforming is a term which has been introduced into common nomenclature of gasification processes in the 1980s. In the most used sense it means the application of an adiabatic low temperature steam reforming step upstream of a conventional steam reformer using natural gas as feedstock. Regarding effect and conditions this process step corresponds to the steam conversion of naphtha in the so-called rich gas process which has been applied for nearly 40 years. Even the same or very similar catalysts are used [34].

Prereforming can be defined as a steam reforming process at limited temperatures ($<$ 700 °C) resulting in an intermediate product gas, the main compound of which is methane besides steam. The process is in thermodynamic equilibrium with respect to the methane (Eq. 8 a) and shift conversion reaction (Eq. 7). The product does not contain higher hydrocarbons. Normally this intermediate gas is further processed in a steam reformer, but in special cases it can also be used for other applications, particularly for the production of fuel gas (e.g., town gas, SNG).

2.4.1. Principles

Prereforming follows the same sequence of reactions as tubular steam reforming characterized by Equations (8), (8 a), and (7). But in contrast to the latter, the equilibrium is established at far lower temperatures. The main feature of prereforming is the irreversible, complete conversion of the higher hydrocarbons fed to the process. Due to the comparably low temperature the main compound of the product gas is — besides unconverted steam — methane. For this reason the

steam conversion of naphtha is called "rich gas process", which reflects the fact that the resulting product gas is rich in methane. The remaining compounds are hydrogen, carbon dioxide, traces of carbon monoxide, and the inerts contained in the feed.

Depending on the feedstock prereforming can be endo- or exothermic. Generally the steam conversion of hydrocarbons to carbon oxides and hydrogen is endothermic. But as prereforming is carried out at only moderate temperatures, the carbon oxides are further converted to methane, a reaction that is highly exothermic. So, if naphtha is used as process feed, prereforming is exothermic whereas in the case of natural gas, the main compound of which is already methane, the overall reaction is endothermic.

2.4.2. Catalysts

As prereforming is a steam reforming process at low temperatures, special catalysts are required to achieve sufficiently high reaction rates. Common properties of these catalysts are a high nickel content (30 – 70 wt %) and a high specific surface (e.g., 200 m^2/g); the support material may be made, for instance, of alumina with minor additions of potassium or magnesium silicate. The geometric form is also adjusted to the special requirements among which the conversion of higher hydrocarbons is the most important. To restrict diffusion ways small pellets (e.g., 5 × 5 mm tablets) are generally used.

Because of the lower temperature, prereforming catalysts are still more sensitive to poisoning than conventional steam reforming catalysts. This is especially true for sulfur poisoning, which is at least partly reversible at the higher temperature level of tubular steam reforming, but irreversible at prereforming conditions. For this reason special care has to be taken in the desulfurization step, the residual sulfur content of which should not exceed 0.2 mg per kilogram of gas. Naphtha is desulfurized by using the refinery-proven technology of hydrogenating desulfurization (see Section 2.2.2).

2.4.3. Prereforming of Natural Gas

Of the different variations of this process, prereforming of natural gas is most frequently used at present. Driving force for the application of this technology is the general constraint for increased economy.

The prereformer is installed upstream of the tubular steam reformer to ease its operation. As all higher hydrocarbons contained in the natural gas are converted, the risk of carbon formation, which is the most critical point in steam reforming, is considerably lowered. This allows the decrease of the steam: carbon ratio and an increase in the heat load on the reformer tubes, which means less energy consumption and smaller equipment. In addition hydrogen is produced by partial conversion of natural gas and furthermore residual traces of catalyst poisons are ab- or adsorbed in the prereformer. This gives, effectively, a catalyst of optimum activity at the inlet of the tubular reformer, where high activity is required most.

Prereforming is generally carried out in adiabatic reactors with a typical inlet temperature close to 500 °C. Due to endothermic hydrocarbon conversion the outlet temperature is lower by 25 to 40 °C, depending of the content of higher hydrocarbons in natural gas. Figure 8 shows a characteristic temperature profile of an adiabatic prereformer.

Figure 8. Characteristic temperature profile in a natural gas prereformer
a) Fresh catalyst; b) Spent catalyst

An option that is frequently made use of in prereforming is the reheating of prereformed gas

Figure 9. Tubular steam reforming with prereformer and reheating of prereformed gas
a) Prereformer; b) Reformer tube; c) Furnace; d) heat recovery

before feeding it to the steam reformer. As steam reforming technology generally has a surplus of thermal energy which can only be utilized for steam generation, this is an additional possibility to improve the overall energy efficiency of a gas production plant. In conventional steam reforming the reintegration of available process heat either from flue or from product gas is restricted by the risk of cracking, that may occur when heating natural gas – steam mixtures to temperatures above ca. 550 °C. This risk depends essentially on the content of higher hydrocarbons. Due to the absence of hydrocarbons except methane and the increased hydrogen content, prereformed gas can be reheated to 650 °C without any problem (Fig. 9).

An alternative to adiabatic operation is carrying out prereforming in heat exchanger type reactors by supplying heat from an outside source. This source can be the product gas of the downstream main reformer (steam reformer or secondary reformer) or the flue gas of the firebox of the steam reformer. In this case the outlet temperature of the prereformer can be up to 700 °C. By this arrangement even more available sensible heat can be reintegrated in the process than by reheating.

2.4.4. Prereforming of Naphtha; Rich Gas Process

The rich gas process is the traditional implementation of prereforming. In addition to prereforming in its actual sense this process has been used particularly for the production of fuel gases during the decades of its application.

Development of the rich-gas (high-methane gas) process started in England in the mid-1950s [35]. Parallel developments took place in Germany and Japan from about 1960. Today, the commercially available processes are those of British Gas, BASF – Lurgi, and Japan Gasoline.

Initially, the process was used mainly for the production of town gas. Soon its advantages were also applied to the production of high-carbon monoxide synthesis gases. In the early 1970s, the rich-gas process was used in the United States to produce substitute (or synthetic) natural gas (SNG).

The rich gas process is carried out commercially at 350 – 550 °C and 1 – 5 MPa. The outlet temperature of a rich-gas reactor is ca. 30 – 100 °C higher than the inlet temperature of the hydrocarbon/steam mixture. Like with prereforming of natural gas the composition of the rich gas can be calculated from the equilibrium constants of the reversible reactions (Eqs. 8 a, 7) according to [36] (see Fig. 10).

The sequence of reactions occurring typically in an adiabatic shaft reactor can be observed by following the temperature profile. At the inlet of the catalyst bed the temperature profile is at first determined by endothermic cracking and gasification reactions, which cause the temperature to drop by ca. 20 °C. Further in the course of the reaction, exothermic hydrogenation reactions prevail, leading to a temperature increase of ca. 60 °C above inlet temperature (Fig. 11).

Figure 10. Equilibrium composition of rich gas C: H = 6; 2.0 kg H_2O per kilogram naphtha
a) 2.5 MPa; b) 4.0 MPa; c) 5.5 MPa

Figure 11. Characteristic temperature profile in a rich gas reactor

During operation, the temperature profile moves through the catalyst bed to the gas outlet. When the upper temperature point (i.e., the end point of the temperature increase) approaches the end of the catalyst bed, naphtha breaks through. Depending on the downstream reaction stage (e.g., tubular reformer or methanation), naphtha breakthrough can be tolerated only up to a certain concentration.

Migration of the temperature profile is caused by exhaustion or blocking of the active nickel centers because of recrystallization, polymer deposits, or catalyst poisoning (sulfur, chlorine, arsenic, etc.). If caused by polymer deposits, this profile migration can be reversed to some extent by regenerating with steam or hydrogen.

Three processes have predominated commercially in the past:

BASF – Lurgi Process. This process is used commercially for the production of town gas, high-carbon monoxide synthesis gas, carbon monoxide, hydrogen, and SNG. The first commercial plants have been in operation since 1965 [37].

This process uses a relatively stable rich-gas catalyst which is fully active as low as 400 °C. Another characteristic of this process is the preferred use of indirectly heated naphtha evaporators.

CRG Process. The catalytic rich-gas (CRG) process is based on developmental work by F. J. Dent (Midland Research Station of the Gas Council). The process was used mainly for producing town gas and SNG over a nickel catalyst on an alumina carrier material. The temperature profile moves almost unchanged through the entire CRG catalyst bed. The first commercial plants have been in operation since 1965 [36].

MRG Process. A special feature of the methane rich-gas (MRG) process is the use of a selective hydrogenation catalyst in the hydrogenating naphtha desulfurization stage, which is capable of operating with hydrogenation gas having a low hydrogen content [38].

Substitute Natural Gas (SNG). The first commercial plants for production of SNG were built in the United States. They use a rich-gas

reactor, generally followed by two methanation stages, carbon dioxide washing, and gas drying. Steam: naphtha ratios of 2.0 kg/kg or slightly higher are applied. An improvement was the installation of a second rich gas stage after the first one. To the second rich gas stage only naphtha is added (in about the same proportion as to the first rich gas stage) or naphtha and only a small amount of steam. Thus, the overall steam: naphtha ratio decreases to ca. 1.1 – 1.4 kg/kg. The temperature range of the second stage varies according to the process. The usual inlet temperature is 350 – 380 °C; the outlet temperature is about 100 °C higher. The two-stage mode lowers steam consumption (i.e., increases efficiency) and the amount of steam to be condensed downstream. It improves the rich gas composition by decreasing the hydrogen content after the second rich gas stage.

Usually, rich gas from the rich-gas stage(s) is cooled to ca. 300 °C and methanated in a shaft reactor under adiabatic reaction conditions by using nickel catalysts. Because undecomposed residual steam in the rich gas is present during this reaction, the process stage is termed *wet methanation.* After cooling and steam condensation, the methane content can be increased further in a second methanation stage (*dry methanation*). The dry methanation stage can be arranged upstream or downstream of the carbon dioxide scrubber (see Section 5.3.3).

The possibility of multistage rich-gas production and multistage methanation offers a great variety of combinations and process alternatives for SNG production. Figure 12 shows the overall diagram of an SNG plant with combined two-stage rich-gas production and single-stage methanation.

Town Gas. The rich-gas process was originally used for town gas production. The standard production concept of town gas from naphtha, with total conversion of naphtha in a rich-gas stage followed by partial reforming of the rich gas in an externally heated tubular reformer to yield a hydrogen-rich gas (see Fig. 13), was developed quite early. Hydrogen-rich reformed gas from the tubular reformer is treated further in the usual manner (CO shift conversion, CO_2 scrubber, etc.).

The ICI method of injecting evaporated methanol into town gas upstream of the high-temperature conversion stage has been applied in some town gas plants as an elegant way of increasing capacity to cover peak requirements in winter. This has enabled the capacity of existing plants to be increased by 20 – 30 %.

Methanol can be converted to town gas in a rich-gas stage. However, in view of the comparatively high price of methanol, this is economically justifiable only for covering peak requirements in winter. Although capital investment costs for the plant are low, the process has found only limited application.

2.5. Autothermal Catalytic Reforming

Catalytic reforming with air or oxygen has been in use longer than either tubular reforming or partial oxidation. Representatives of this first generation technology are the ONIA-GEGI and the SEGAS processes, both used for the production of fuel (town) gas. Feedstock in these cases was gas oil or even crude oil, resulting in a high deactivation rate of the catalysts in use by coking. Correspondingly these processes were operated discontinuously with periodic regeneration. Plant designs today, however, differ substantially from this type of plant, as target product (syngas) as well as feedstock (natural gas) have changed completely and continuous operation is a "must".

Characteristic for autothermal reforming is the high flexibility of the process. This generally enables a wide range of reaction conditions with regard to feedstock, steam: carbon ratio, temperature and pressure. Typical operating conditions are outlet temperatures close to 1000 °C and pressures between 3 – 4 MPa. Suitable feedstocks are natural gas, LPG, and naphtha up to a boiling end point of ca. 200 °C. Furthermore autothermal reformers are often fed with gases, which have already passed a steam reformer ("primary reformer"). In this case, the autothermal reformer is called "secondary reformer". Today, the combination of tubular steam reforming and autothermal reforming is the standard technology for the production of ammonia synthesis gas. Autothermal reforming is more flexible than tubular reforming because the higher allowable operating temperature can compensate for any increase in methane slip which higher pressure would otherwise cause. Furthermore, the higher

Figure 12. SNG plant

operating temperatures can also compensate for a wider equilibrium approach (difference between actual and equilibrium temperature at the reactor outlet) which may be caused by mild sulfur poisoning of the catalyst. The maximum operating temperature is not limited by the tube material, as in tubular reformers, but only by the stability of the catalysts and the refractory lining of the reactor.

Oxidizing agents may be oxygen or air. The selection depends on whether the presence of nitrogen in the reformed gas is desirable, e.g., for the production of ammonia. By proper partition of primary reforming and secondary reforming with air, a final syngas with stoichiometric hydrogen: nitrogen ratio is obtained. The application as secondary reforming in ammonia synthesis is by far the most frequent commercial application of autothermal reforming.

There are two versions of the process differing in reactor design and arrangement of the catalyst bed. In one type of reformer the reactants (feedstock, steam, and oxygen or air) are discharged directly from a mixer to the catalyst in a fixed bed reactor. In the second type the mixer acts as a burner discharging into an empty, usually conical space above the catalyst bed, which only fills the lower portion of the reactor. The latter modification has generally proven as the more versatile and is used predominantly.

Typical applications of the two versions of the process are compared in Table 10. A methane tail gas was selected as feedstock for the all-catalytic version, whereas reformed gas from a tubular reformer for the production of ammonia synthesis gas (typical use of a secondary reformer) was employed for the version with precombustion.

Table 10. Data for two reformed gases obtained by autothermal reforming

	Methane tail gas reforming with oxygen addition	Reforming with air addition and precombustion (secondary reformer)
Gas for reforming		
Composition, vol %		
CO_2		7.11
CO	3.90	4.25
H_2	1.80	34.32
CH_4	80.00	3.90
C_2H_4	0.25

Reformed gas (moist)		
Flow rate, m^3/h	251 450	196 000
Pressure, MPa	2.65	2.97
Temperature, °C	925	965

The catalysts used consist of thick-walled Raschig rings 16 mm in diameter and height, having a hole of 6 – 8 mm in the middle (standard size). The nickel content is about 3 – 12 wt %. Aluminum oxide (preferably the α-modification) is used as carrier material, and the content of silicon dioxide should be < 0.2 % because of its volatility with steam.

Figure 14 shows the design of a modern commercial autothermal reformer. The refractory lining is almost always multi-layered; high-strength bricks or other lining materials (castables) are used on the hot face, whereas materials of lower bulk weight and high insulating capacity are used on the cold face (inner wall of pressure vessel). Special attention must be paid to ensuring a close fit between lining and pressure vessel (vapor stops), because the considerable pressure drop in the catalyst bed involves the danger of bypass streams between lining and pressure vessel, which can lead to overheating (see Fig. 14). In one frequently used modification the reformer is provided with a water jacket that generally cools at atmospheric pressure but occasionally is slightly pressurized.

Figure 14. Autothermal reformer (secondary reactor)
a) Burner; b) Refractory lining; c) Water jacket; d) Catalyst; e) Grid

The catalyst grid is usually made of heat-resistant refractory material. Catalyst can be removed by suction from the top.

The burner (mixer) is the most critical part of the autothermal reformer. This is true for both types of reactor design. In most cases, the burner is designed as a single-tube mixer. Various types of burner nozzles are available, all intended to

produce a homogeneous mixture of the oxidant (oxygen or air) and the gasification agent before they enter the catalyst bed. The burner internals are made of highly heat-resistant steel or cast steel; some burner types are cooled.

To achieve sufficient mixing of the different inlet gas streams is a special problem in the *flameless version* of the process, because a certain free space below the mixer is required. As linear gas velocities have to be high in this area to avoid ignition, the mechanical stress on the catalyst is high, leading to abrasion and disintegration. This effect causes an increase in the empty space below the mixer that has to be compensated for by periodical refilling of catalyst during operation which is difficult to perform. The advantage of this operation mode is that the maximum temperature in the reactor does not essentially exceed the adiabatic end temperature (reactor outlet temperature).

In the *open flame version* of autothermal reforming generally a good mixture of the feed gases is achieved. The problem to be solved in this case is to keep the flame, which has temperatures even in excess of 3000 °C, away from the reactor wall and the catalyst surface. An enormous progress has been made in the last years by applying model calculations (Computational Fluid Dynamics) for burner and flame [39]. Therefore, this modification of autothermal reforming has become the clearly superior technology.

Besides ammonia synthesis — where autothermal reforming (secondary reforming) is standard technology — and a specific application in the gasification of Fischer – Tropsch tail gas, autothermal reforming is also applied in some large-scale methanol plants. The syngas production in these cases follows the mode of "combined reforming", a combination of tubular steam reforming and autothermal reforming comparable to ammonia syngas production. Combined reforming enables the production of a syngas with an optimum ratio of hydrogen to carbon oxides and minimizes the feed gas consumption in this way. However, pure oxygen is required as oxidant. This requires additional investment cost, if the oxygen has to be produced on site. Therefore combined reforming is economical particularly for large-size plants with a capacity above 1000 t/d (see Section 7.1).

As already stated, a main advantage of autothermal reforming is the "cold" shell of the reactor, which allows the application of high reaction temperatures and pressures. Whereas a temperature close to 1000 °C is already a certain limit in view of the heat resistance of the used catalysts, the potential of applying higher pressures is not yet finally utilized. Pressures up to 8 MPa, usual in noncatalytic partial oxidation, seem to be possible also for the catalytic version and will make it increasingly attractive in the near future. The design of a plant with one pressure level for syngas production (only autothermal reforming) and methanol synthesis has been patented.

3. Noncatalytic Partial Oxidation and Special Gasification Processes for Higher-Boiling Hydrocarbons

3.1. Raw Materials

Partial oxidation is the most commonly used process for gasification of heavy oil although virtually all hydrocarbon mixtures regardless of origin, are suitable feedstocks.

Crude Oil, Crude Oil Distillates and Residual Oils. Crude oil (→ Oil Refining) is a mixture of many different types of hydrocarbon. These can be classified in one of three ways: as alkanes, (and isoalkanes), naphthenes, and aromatics; by the number of carbon atoms in the molecule; or by their boiling point, which is approximately proportional to this number. However, crude oils also contain varying quantities of other substances, which also play a role in the usability of the oil and, especially, of the residue. The most important impurities are sulfur compounds; others are oxygen- and nitrogen-bearing components, as well as minerals (sand and dissolved salts).

In addition, some impurities not naturally present in the crude stem from its transportation; the main example is water, usually seawater with a high salt content. Residual oils may also contain impurities that arise from wear of catalyst, refractory material, and equipment in conversion units.

As a general rule, low-boiling components are distilled from the crude oil and marketed as

light naphtha, heavy naphtha, kerosene, and gas oil. However, some crudes contain only small amounts of light ends; the extremes are plastic asphalts (→ Asphalt and Bitumen). These resources, from which marketable products can be obtained only by applying expensive refining techniques, are suitable as feedstocks for partial oxidation with practically no pretreatment, except removal of water, salts, or solids.

Crude oil distillates in the boiling range of ca. 35 – 360 °C are valuable raw materials for the chemical industry and are also processed into motor fuels or used as light fuel oil. Like crude oil, these distillates are used for gas production only in special cases, for example, if a surplus of various distillates cannot be balanced out in the refineries.

The gas recycle hydrogenator (see page 51), in which only hydrocarbons with a final boiling point $\leq$ 325 °C can be gasified, is an example of the way in which process considerations can restrict feedstock suitability.

Residual oils are the preferred raw material for partial oxidation. First, they are generally cheaper than distillates; second, the percentage of residues that cannot be used for combustion purposes is increasing because of pollution control. For example, in some places, power stations are only permitted to burn heavy oils with a sulfur content $<$ 0.8 %.

Refinery technology, too, contributes greatly to the increasing quantity of high-boiling, high-sulfur residues. To recover an ever-increasing proportion of light and middle distillates from crude oil, processes have been developed that also enable recovery of naphtha and gas oil from distillation residues. Among these processes are liquid-phase cracking (→ Oil Refining, Chap. 3.2), catalytic reforming (→ Oil Refining, Chap. 3.4), solvent deasphalting (→ Oil Refining, Chap. 3.6), and hydrocracking (→ Oil Refining, Chap. 3.5). In some cases, the residue from these processes may even be solid coke; it contains practically all the impurities in crude oil, apart from those sulfur compounds that have already been driven off during distillation and salt from seawater, which is removed beforehand in the desalter.

On assessing the suitability of residual oils for gasification, the quantity and type of ash, feedstock viscosity, and above all, the ratio of alkalis to vanadium which is important for the lifetime of the refractory lining must be considered. Properties such as boiling range, carbon – hydrogen ratio, and sulfur content do not influence suitability but are important for assessing design parameters. Some typical residual oils and other feedstocks currently used for partial oxidation are listed in Table 11.

Other Feedstocks. In addition to crude oil and its manifold products, a number of other hydrocarbon mixtures, as well as carbon- and hydrogen-rich compounds, are used for gasification of heavy oils. Chief among these are certain liquid byproducts from coal gasification and upgrading.

In gasification of bituminous coal by the Lurgi pressure gasification process (see Section 4.4) aqueous condensates as well as medium oils and coal tar are obtained as byproducts. Medium oils have a variety of uses, but the generally fluid tar can only be recycled to the gasification reactor or used as a feedstock for heavy-oil gasification. Precleaning, at least by settling, is necessary because of the generally high ash content of the tar, which may be as much as 15 %.

Lignite tar oil is a byproduct of the carbonization of lignite or lignite briquettes. Like coal tar, it may contain a larger or smaller quantity of dust, depending on the nature of the raw material and the characteristics of the carbonization process. Carbonization of lignite is uneconomic today. However, certain plants are still operated; in some cases, the char and lighter condensation products are sold and the lignite tar oil is used as a feedstock for gas production by partial oxidation. In gasifying coal and lignite tars, attention must be paid to the content of low-melting ash, which may require slagging operation.

In a few cases, undesirable or unsalable *byproducts of synthesis processes* are used for partial oxidation, preferably when the gas produced by oil gasification is suited to such synthesis processes. An example of this is oxo synthesis, in which oxo alcohols and various byproducts are produced from propylene and carbon monoxide: hydrogen mixtures. One of these byproducts is isobutyraldehyde, which is formed in considerable quantities. It has already been used for partial oxidation with great success.

The heavy products of *tar sand extraction* (→ Tar Sands) and *oil shale retorting* (→ Oil Shale)

Table 11. Specific data for typical feedstocks (basis: Lurgi oil gasification, gasification pressure: 6 MPa; no soot recycle)

Feedstock properties	Feedstock type				
	Natural gas	Vacuum residue	Propane asphalt	Petroleum coke (35 % water)	Orimulsion [a] (29 % water)
Specific gravity (15 °C)		1.05	1.14	1.03	1.002

may also be suitable as feedstocks. Their use, however, lies in the future.

Natural gas is still used as a feedstock for the production of synthesis gases with a higher ratio of carbon monoxide to hydrogen than is achievable by steam reforming. For economical reasons, partial oxidation of natural gas is used in small plants and in regions where natural gas is cheap. Lately it is considered as a means of converting "*stranded gas*" into marketable liquid products like methanol or synthetic fuel.

3.2. Partial Oxidation of Hydrocarbons

3.2.1. Principle

Partial oxidation is, in principle, the reaction of hydrocarbons with an amount of oxygen insufficient for complete combustion at temperatures between 1600 and 1350 °C and pressures up to 15 MPa. It operates as a continuous process. The basic reactions are as follows:

$$C_nH_m + n/2\,O_2 \rightleftharpoons n\,CO + m/2\,H_2 \quad (13)$$

$$C_nH_m + n\,H_2O \rightleftharpoons n\,CO + (m/2+n)\,H_2 \quad (14)$$

$$C_nH_m + n\,O_2 \rightleftharpoons n\,CO_2 + m/2\,H_2 \quad (15)$$

The minimum amount of oxygen required for complete conversion of the hydrocarbons is indicated by Equation (13); 0.5 kmol of oxygen is required for every kilomole of carbon. If the reaction proceeds according to this equation, when high-boiling distillates or residual oils (i.e., feedstocks with a large number of carbon atoms per molecule) are being gasified sufficient heat is generally produced to warm the reactants to about 1500 °C. Carbon monoxide and hydrogen are the main products until the hydrocarbons have been completely converted; only then can carbon dioxide and water be formed from

surplus oxygen. Opinions differ on the reaction sequence; some test results indicate that carbon dioxide and water are primary reaction products [40].

To prevent excessive temperature increase, steam is usually added, which reacts endothermically with the hydrocarbons according to Equation (14). This leads to the formation of more hydrogen than would be expected from conversion according to Equation (13).

The main elements of the hydrocarbon mixtures — carbon, hydrogen, oxygen, and sulfur — are converted independent of the nature of the feedstock, to the following thermodynamically stable compounds: carbon monoxide, carbon dioxide, hydrogen, water, methane, hydrogen sulfide, and carbonyl sulfide. The proportions of various components in the gas mixture are determined by a range of equilibria, which include the shift conversion:

$$CO + H_2O \rightleftharpoons CO_2 + H_2 \tag{7}$$

the methane equilibrium:

$$CH_4 + H_2O \rightleftharpoons CO + 3\,H_2 \tag{8a}$$

the hydrogen sulfide – carbonyl sulfide equilibrium:

$$H_2S + CO_2 \rightleftharpoons H_2O + COS \tag{16}$$

and

$$CO + 1/2\,O_2 \rightleftharpoons CO_2 \tag{2}$$

$$CH_4 + CO_2 \rightleftharpoons 2\,CO + 2\,H_2 \tag{11a}$$

These equilibria are largely established in the gasification reactor between 1500 and 1350 °C. They remain practically unchanged during very rapid cooling by quenching with water or by indirect heat transfer to water boiling at a comparatively low temperature. Below 900 °C, even an approximation to equilibrium could be achieved only by accepting very long residence times or by using catalysts. The latter cannot yet be applied commercially because of soot formation. The principal advantages of partial oxidation are (1) the possibility of converting hydrocarbons that cannot be vaporized and (2) the complete destruction of all carbon – carbon bonds; the only hydrocarbon remaining in the raw gas is methane.

Methane formation is about ten times as high as indicated by Equation (8 a); this is probably due to the slowness of the reaction according to Equation (11 a). As expected, increasing pressure promotes methane formation; at 1400 °C and 3.0 MPa, the methane content of the product gas is ca. 0.3 vol %, whereas it is 0.55 vol % at 6.0 MPa. Methane content is also influenced by changes in reaction temperature and addition of larger or smaller amounts of steam.

Under conditions prevailing in the reaction zone, no free carbon should be present, according to either the Boudouard equilibrium

$$C + CO_2 \rightleftharpoons 2\,CO \tag{10}$$

or the reaction

$$C + H_2O \rightleftharpoons H_2 + CO \tag{6}$$

Soot can be present in the raw gas only at below 1200 °C and around 5.0 MPa. Whereas the amount of soot produced during partial oxidation of methane is practically zero, in heavy-oil gasification about 0.5 – 2.5 mass % of feedstock is contained in the raw gas as free carbon. Some authors assume that this soot formation is due solely to thermal cracking of a proportion of the hydrocarbons; others attribute it partially to the Boudouard limit being reached during cooling. Ash particles in the heavy oils also seem to act as nuclei of condensation or catalysts for soot formation [41, 42].

In heavy-oil gasification, soot formation can be nearly eliminated by increasing the reaction temperature, at the cost of a considerable increase in oxygen consumption and a corresponding increase in carbon dioxide content at the expense of carbon monoxide.

Sulfur components of the gas mixture are largely hydrogenated according to Equation (16). Under normal reaction conditions, ca. 95 % of the sulfur is converted to hydrogen sulfide and the remaining 5 % to carbonyl sulfide. No sulfur di- or trioxide is detectable in the raw gas from partial oxidation.

3.2.2. Types of Processes

Three processes are commercially established for the production of gas mixtures (primary components: H_2 and CO) from gaseous or liquid hydrocarbons by partial oxidation: the Texaco, the

Shell, and the Lurgi process. The main steps of all three processes are now practically identical.

The original differences between the processes were that Texaco used natural gas as the sole feedstock and changed to liquid hydrocarbons only after the process of steam reforming of natural gas became available, whereas Shell used heavy oils from the beginning. Lurgi's process in contrast was developed for lignite tar oils and slurries and covers now the broadest range of feedstocks.

What still distinguishes the processes today are the methods of heat recovery and soot management. While all three use boiler configurations for high-grade heat recovery, only Texaco and Lurgi have available quench configurations for heavy-duty services. On the other hand, all three can offer some kind of soot recirculation system while only Lurgi and Shell have built more economic once-through systems, which are also environmentally favorable.

Over 320 plants operating on these three processes have been built to date.

Texaco Process. Originally, the Texaco process did not have a waste-heat recovery boiler (Fig. 15). Feedstocks are preheated as in the other two processes. Fired heaters are often preferred to steam-heated ones for heavy oil as well, probably by analogy with natural gas cracking practice. Besides partial oxidation of natural gas and residue oil, this process has been developed further for partial oxidation of coal slurries (for details, see Chap. 4).

Process steam is used to atomize the heavy oil in the reactor, so the oil must be pressurized to only a few bars above reactor pressure.

Oxygen is supplied to the reactor through a central tube; the oil – steam mixture is fed coaxially through an annular gap. The gas mixture leaving the reaction zone is cooled to 250 – 300 °C by quenching with hot water in a quenching section of the reactor. Most of the soot and ash is removed from the gas at the same time, whereas the water vapor content increases considerably due to evaporation of part of the quench water. The water vapor content of the gas is sufficient for conversion of the carbon monoxide to a residual content of ca. 1.8 – 2.5 vol % in a downstream high-temperature conversion unit.

After leaving the quenching tank, the gas is scrubbed again in a special venturi tube and a soot scrubber (a packed column), which remove the soot to a residual content of 1 – 2 mg/m^3. If the gas is to be fed to a high-temperature conversion unit, the soot is scrubbed out with hot water.

Shell Process. The basic flow sheet of this process resembles the one presented in Figure 16. The processes differ in the burner technology, the soot removal and the soot/ash management. The Shell process was right from the beginning equipped with a waste-heat boiler and is still available in this configuration only.

By means of reciprocating or centrifugal pumps the heavy oil feedstock (as single stream) is fed through a preheater to the reactor. The so-called co-annular burner is of the steam-atomizing type: oil, steam – oxygen mixture and steam are routed through concentric, alternating channels (slits) whose number determines the capacity. Oil viscosities at the burner of up to 300 mm^2/s are manageable. The burner is cooled by a pressurized circulating cooling water system.

The refractory-lined reactor and the waste-heat recovery boiler are similar to those of the other processes. Soot is removed from the raw gas in two stages: most of it is washed out with water in a quench tube [instead of the venturi scrubber d) of Figure 15] and collected in a soot separator. In the scrubber, a packed column, the remaining soot is removed to a residual content of < 1 mg/m^3. Preferably soot-free water from the soot recovery unit is supplied to the top of the scrubber, and soot-laden water from the scrubber outlet is used for the quench tube. By cooling the water fed to the scrubber, the gas is cooled to slightly above ambient temperature. The soot slurry is treated in a once-through soot/ash recovery and management system as described below.

Lurgi Process. This process was originally developed for the gasification of tars, oils, and slurries formed as byproducts of fixed bed gasification. This lends to an inherent robustness (as in slagging service) and flexibility (digesting unmixable feeds) which the refinery-derived processes are lacking. The Lurgi process is available in both, quench and boiler configurations.

Figure 16 shows the boiler configuration of the Lurgi process with metals ash recovery system. The feedstock is fed through preheaters

(a) to the reactor (b) by centrifugal pumps (or reciprocating pumps for smaller capacities). A pressure of only about 0.5 MPa above reactor pressure is needed for operation of the steam-atomizing burner. Preheating of feedstock and oxygen is mainly done for optimization of the process heat balance, i.e., to save on the costs of heavy oil and oxygen otherwise consumed for internal heating. The lowering of feedstock viscosities is an additional — but welcome — effect. The burner itself works well even with viscosities up to 500 mm^2/s, meaning that every pumpable feedstock can be gasified. This top mounted multi-gun burner has the capability of handling different, unmixable fluids, e.g., emulsions and slurries in addition to heavy oils. The broken feed line represents such an optional secondary feed.

The oxidant is preheated as well and mixed with steam as moderator prior to being fed to the

burner. The burner and reactor are tuned by fluid-dynamic simulation to achieve mixing of this mixture with the feedstock within the smallest possible volume. Thus, the reactor space is optimally used for gasification to completion. The burner is water-cooled using a dedicated circulating cooling water system at a pressure above that prevailing in the reactor. The entire reactor is refractory-lined. In the nonslagging service associated with boiler operation a refractory material with high alumina content has achieved the longest lifetimes.

The raw gas leaves the reactor at about 1350 °C and passes directly into the heat recovery boiler (c) where 10 – 14 MPa steam is formed while cooling the gas to a few degrees above saturated steam temperature. This boiler is specifically designed for the high gas inlet temperatures and the particulates-charged gas at high velocities. A small part of the steam thus generated is used for feedstock and oxidant preheating, the bulk is superheated for use in steam turbine drives or in a combined cycle power plant. The rest of the heat is recovered in a boiler feed water economizer. Commonly, most of the heat content of the gas below the dew point is used to heat up make-up water or turbine condensate in a water preheater after the venturi scrubber.

The raw gas from the reactor contains a certain amount of free carbon (soot). The plant is normally designed for a soot content in the gas equivalent to 0.5 wt % of hydrocarbon reactor feedstock. The soot in the gas is removed in a two-stage water wash, which consists of a venturi scrubber (d) and the fine wash scrubber (e). The gas leaves the scrubber at 40 °C at a residual soot content < 1 mg/m^3. The soot slurry, which has an ash-soot content of 1 wt % carbon, is routed to the metals ash recovery system (MARS, see below).

The Lurgi oil gasification is also available in the *quench configuration* where the hot reaction gas is brought down rapidly to saturation temperature by direct water quench. This quench can be selected for slagging service as in the original application (coal – oil slurries, wastes) or for the less severe high-ash, high-salt residue service. In slagging service the reactor is lined with a special high-chromium refractory which has proven its resistance in many years of operation.

Like in the Shell process, the gas mixture produced contains approximately equal proportions of carbon monoxide and hydrogen, ca. 5 % carbon dioxide, and small amounts of methane, nitrogen, argon, and hydrogen sulfide. Although not equally well suited to all syntheses (meaning those that require CO and H_2, as well as those that require one of the two, either alone, or either mixed with a third gas such as N_2), its composition is nevertheless neutral for many uses. Methanol synthesis gas or hydrogen can be produced by converting part or all of the carbon monoxide. If the necessary amount of nitrogen is added, ammonia synthesis gas can be produced. If the hydrogen – carbon monoxide ratio remains unchanged, the gas is suitable, after purification, for oxo synthesis and for production of maximum quantities of carbon monoxide by low-temperature separation or absorption.

Soot/Ash Recovery and Management. In the Texaco process, soot is extracted from the soot water with naphtha in a closed system and recovered for recirculation to the reactor. Shell used an open system based on pelletizing in its original process but was subsequently obliged to change to a closed system also based on extraction with naphtha.

Due to difficulties with increased viscosities of very heavy feedstocks, which makes carbon recycle impossible, and due to poorer economics of the recycle processes, once-through systems were developed by Lurgi and Shell. These systems basically incinerate the soot after filtration and recover the heavy metals as oxides.

Texaco Method (Fig. 15). Soot water is mixed with naphtha, the soot and some of the ash passing into the naphtha phase. After the two phases are separated, practically soot-free water from the decanter is depressurized in a flash tank, to drive off dissolved naphtha. Naphtha is recovered by condensation and recirculated to the process; the same is true for naphtha-free water.

The naphtha – soot mixture from the decanter is mixed with heavy oil, and naphtha is distilled off overhead in a distillation column. Oil collects at the bottom of the distillation column together with some ash and a residual amount of naphtha. The oil is mixed with more heavy oil and fed to the reactor via the oil heater.

Lurgi Metals Ash Recovery System (MARS, Fig. 16). The problem of uneconomic carbon recycle was solved by Lurgi through application of its vanadium roasting technology. A proprietary multiple hearth furnace is used for controlled combustion of the soot under conditions where the vanadium oxides neither melt nor corrode.

The soot slurry from the gasification (in both, quench and boiler configurations) is flashed to atmospheric pressure in a slurry tank (f). The slurry is filtered (g) leaving a filter cake with about 80 wt % residual moisture and a clear water filtrate, which is partly recycled as quench or scrubbing water. The filter cake is subjected to a controlled incineration process in a multiple hearth furnace (h). The product contains typically about 75 wt % vanadium pentoxide (plus the nickel and iron from the crude), which can be sold to metal reclaimers. The process is autothermal, the heat of combustion being sufficient to evaporate the moisture content of the filter cake. Excess water is stripped of dissolved gases in a wastewater stripper (j) and pumped to final treatment.

Shell Method. Shell uses a similar system of filtration and incineration. The main distinctions to the Lurgi process as described above are in the selection of key equipment like furnace and filters.

Selection Criteria for Quench Configuration Versus Heat Recovery Configuration. In addition to process-specific marketing strategies there are technical and economic criteria for the selection between quench and boiler configurations (see Table 12). These must be studied carefully for every application of the Texaco and Lurgi processes that alone offer alternatives.

Generally speaking, the heat recovery configuration can be selected when the feedstock contains low amounts of precipitation-prone contaminants, which could block the boiler tubes. Most refinery heavy residues fall in this category. In this case it is possible to run the gasification at highest efficiency by generating considerable amounts of high-pressure steam, which also yields highest efficiency in a possible downstream integrated gasification combined cycle (IGCC) power plant. The additional investment in the boiler is recovered quickly.

Table 12. Comparison of quench and heat recovery configuration

	Quench configuration	Heat recovery configuration
Feedstocks		
Gas, residues, wastes, slurries (sludges, coal, coke), extreme ash and/or salt contents	highest flexibility	limited by possible salt precipitation
Product range:		
$H_2 + CO$, H_2, CO	fastest (cheapest) route to H_2 and NH_3	highest flexibility
Energy utilization:		
Steam production	MP * steam available trade off efficiency vs. cost	HP ** steam, heat recovery at highest temperature, highest efficiency for IGCC possible
Investment cost:	lowest cost for gasification unit	HP ** waste-heat boiler (high efficiency) at extra cost

* MP = medium pressure.
** HP = high pressure.

On the other hand, should the feedstock contamination be above the waste heat boiler's limits, the quench configuration has to be chosen. It also may be selected when such contaminated feeds are expected in later operation of the refinery or, when the customer wants to keep open all options for feedstocks like coke/coal slurries and wastes. The quench configuration thus offers highest (potential) flexibility at lowest investment cost traded off against a loss in energy efficiency.

The product side also influences the selection, e.g., for hydrogen or ammonia as product it is more economical to route the quenched, i.e., hot saturated gas directly into a raw gas shift conversion unit (see Section 5.1) instead of cooling it down and desulfurizing it before the shift. This is because the water quench raises all the steam necessary for the CO shift reaction directly within the reactor effluent. If a syngas rich in CO is required, the heat recovery configuration is the appropriate choice.

3.2.3. Influencing Raw Gas Composition

Different types of gas are produced not so much by changing operating conditions (e.g., pressure and temperature) as by changing the proportions of reactants, adding carbon dioxide, and employing further process steps immediately downstream of actual gasification. Commercially produced gases can be classified in

three large groups: synthesis, fuel, and reduction gases.

An overview of gas yields and compositions in relation to the feedstock and gasifying media, together with other important data, is presented in Table 13.

Synthesis Gas. Synthesis gas must nearly always be low in undesirable gas components such as methane, nitrogen, and argon, and high in either carbon monoxide or hydrogen, or both. Medium to high pressure is desirable as well. Whereas the nitrogen and argon contents of unpurified synthesis gas depend almost exclusively on the quality of air separation (nitrogen components of heavy oils generally cause a rise of less than 0.1 % in the nitrogen content of the gas), the methane content is largely a function of gasification pressure (see Section 3.2.1).

The proportions of gasification steam, oxygen, and heavy oil are the same for almost all synthesis gases, regardless of whether hydrogen- or carbon monoxide-rich gases or gases with a defined ratio of hydrogen to carbon monoxide are produced. For the last category, which includes primarily synthesis gases for the production of oxo alcohols, carbon dioxide must be recycled to the reaction zone to increase the carbon monoxide content of the synthesis gas and obtain the correct ratio of hydrogen to carbon monoxide (which can range from 1: 1 to 1: 1.5 for certain oxo processes).

To manufacture synthesis gases in which no (or only partial) conversion of carbon monoxide to hydrogen and carbon dioxide with steam occurs, use of the waste-heat boiler to cool the hot reformed gas is preferred to quenching with water or steam. Examples are gases for carbon monoxide production, some oxo processes, and methanol synthesis.

A special case is *partial conversion* of carbon monoxide immediately following the gasification reaction. This can be brought about by quenching with defined quantities of water or steam, either in the bottom section of the gasification reactor or in a quench tube located between the reactor and the waste-heat boiler.

Here, best results are achieved by using steam and cooling the gas to ca. 1000 °C. At lower temperature, the water gas equilibrium, (Eq. 7) cannot be reached without a catalyst. A very flexible and economic alternative is the use of a direct quench reactor in parallel to a reactor/waste-heat boiler train.

If, on the other hand, production of hydrogen-rich synthesis gas is desired, *direct quenching* of the hot synthesis gas, followed by catalyst-based shift conversion is the preferred route. An example is the production of ammonia from heavy oil in countries with cheap coal reserves and little oil of their own, (e.g., India), which are able to supply coal-based energy at low cost (whether directly from steam or indirectly via electric power).

Oxygen with a purity of $> 95\,\%$ is used for gasification. In fact, the oxygen content is usually $> 99\,\%$, because the cost of achieving the higher purity is always less than the extra cost of gas purification and synthesis (e.g., by additional consumption of synthesis gas) to compensate for hydrogen or carbon monoxide losses from increased discharge of purge gas.

The possibility of manufacturing ammonia synthesis gas from heavy oil by gasification with enriched air (i.e., with a $N_2 - O_2$ mixture containing $> 21\,\%\ O_2$) has also been proposed but not exploited commercially. The higher costs of purifying and conditioning the gas that result from the increased volume of synthesis gas because of its nitrogen content outweigh the savings in gasifying medium. (Enriched air can be produced from air by mixing with pure oxygen or by adsorptive depletion of nitrogen.)

Fuel Gas. In contrast to synthesis gas production, a low content of inerts is not particularly important for the manufacture of fuel gas. Only the required heating value determines the gasifying medium, pure oxygen or air. Combustion of larger volumes of gas instead of gas with an increased heating value is often justifiable economically. However, not only the heating value but also the density and thus the Wobbe index (see Section 8.2.1.3) of the fuel gas are almost always stipulated for reasons of interchangeability with fuel gases from different sources. When fuel gases containing carbon monoxide are used in the private sector, it is mandatory to minimize their toxicity by limiting the carbon monoxide content, generally to between 1 and 3 vol %.

Hot Carburetion. Fuel gas specifications for the private sector require heating values ranging from 17 500 (town gas) to 34 000 kJ/m^3

Table 13. Typical results of partial oxidation (basis: Shell gasification)

(natural gas). However, gasification of heavy oil produces heating values of only 4000 – 11 000 kJ/m^3, depending on whether air or oxygen is used as the gasifying medium. Thus, the heating value must be improved. This can be achieved — after appropriate gas conditioning — either by methanation without addition of other fuels or by hot carburetion with addition of liquid hydrocarbons having a low final boiling point. Methanation is necessary if heating values > 20 000 kJ/m^3 are required. For the production of town gas with heating values between 16 500 and 19 000 kJ/m^3, however, hot carburetion is more beneficial from the heat economy aspect, because it operates with practically no addition or subtraction of heat. This is in contrast to the strongly exothermic methanation process, in which about 10 500 kJ (i.e., ca. one-fifth the heating value of the feedstock) must be dissipated per cubic meter of methane formed.

Due to the widespread availability of natural gas — in some places as LNG — carburetion has lost most of its significance as a commercial process.

As can be calculated with the aid of Table 13, the thermal efficiency (i.e., ratio of the heating value of the product gas to the heating value of the fuel) is 81 % for normal gasification and increases to 89 % with hot carburetion, at the expense of reduced generation of steam from waste heat.

Fuel Gas for IGCC Power Plants. A special area of fuel gas production is for gas turbines in power plants. Due to increasingly stringent air pollution control regulations, operating coal- or oil-fired steam boilers without flue gas desulfurization systems is impossible. Because cleaning large gas volumes at slightly above atmospheric pressure is very expensive, attempts have been made to find a more economic solution by

applying fuel gasification with subsequent gas cleaning under pressure. As shown in Figure 17, partial oxidation of heavy oil can be combined beneficially with a gas turbine-driven generator, not only from the point of view of gas cleaning but also with regard to generation of high-pressure steam. For the arrangement illustrated, an efficiency well above 46 % is achieved, 2 – 4 % better than for a conventional steam boiler power plant [43].

IGCC Power Plants (Fig. 17). A heavy refinery residue is gasified with oxygen from an air separation unit (i) in a Lurgi oil gasification plant (a) at 6.5 MPa, producing a lean gas with a heating value of 11 000 kJ/m^3. Oxygen and residue are preheated to 280 °C. Cooling in the waste-heat recovery boiler produces high-pressure steam at 13.0 MPa. After the soot is removed as described above and the gas is cooled, carbonyl and hydrogen sulfides and all other trace contaminants are removed to 20 ppm in one step in a Lurgi Rectisol unit (b) (see Section 5.4.2.1). The desulfurized gas passes through a gas expander (f) generating electric power and refrigeration to cool the methanol within Rectisol. This *dual use expansion* adds significantly to the overall efficiency of power generation.

The low-calorific gas is burned in a gas turbine (d). For NO_x-control the gas is further diluted by saturation with water and — optionally — with nitrogen from the air separation unit. Waste heat from the gas turbine off-gas and the saturated steam from the gasification are used in the waste-heat steam generator (h) to produce additional steam and to superheat steam. The energy of the superheated steam is used in a condensing steam turbine (g) that drives a generator (e). For maximum efficiency the steam system will be designed for three levels with one or two reheat stages.

The gas turbine is also coupled to an air compressor in which combustion air for the gas turbine is compressed. A part of this compressed hot air can be routed through a cooler – saturator system producing steam for fuel gas saturation before entering a medium pressure air separation saving the separate air compressor. The nitrogen from the air separation in turn can be recycled back to the gas turbine for NO_x-control and to maintain the mass flow of the turbine. Air and nitrogen integration as described yields higher efficiency than a nonintegrated system with independent air separation unit (ASU) compressor, but involves increased complexity of the plant. Therefore different designs with varying degrees of integration exist to accommodate for all requirements. Many versions of this IGCC process exist, some of which export steam or synthesis gas together with electrical power. Coproduction of this type results in better overall economics for a plant.

A good example for this concept is a reference plant for the Lurgi oil gasification (SVZ, Schwarze Pumpe, Germany) where the oil gasifier together with coal-waste gasifiers produces a synthesis gas which is fed to a combined cycle and a methanol plant [44]. Another example is a large refinery in Pernis (The Netherlands) where a Shell gasification feeds two thirds of its capacity to a hydrogen production plant and one third to an IGCC power plant [45].

Reducing Gas. Gas produced from heavy oil is also used in ore reduction. The carbon dioxide and water vapor content or reducing gases must be as low as possible. Water vapor can be removed easily from the gas by condensation, which presents no problem if the gas has been freed of soot, sulfur, and carbon dioxide. However, for reduction of less sensitive ores, uncooled or only partly cooled, soot-laden gas manufactured from low-sulfur oils is used whenever possible. Thus, water vapor content may be an important element of the gas composition. The quality of reducing gases is measured by the degree of oxidation η, which is defined as follows:

$$\eta_0 = \frac{(c_{H_2O}+c_{CO_2})\cdot 100}{c_{H_2O}+c_{CO_2}+c_{H_2}+c_{CO}}\ (\%)$$

Degrees of oxidation $\leq 5\,\%$ are the goal (see Table 13).

Reducing gases, which are always produced directly alongside the ore reduction furnace, differ from synthesis and fuel gases in pressure and temperature. Synthesis and fuel gases must be maintained at high pressure and below ambient temperature: for synthesis gases, with regard to gas purification and compression; for fuel gases, with regard to gas purification, distribution, and storage. For admitting reducing gas to the shaft furnace, a slight overpressure is sufficient; on the other hand, a temperature up to 1000 °C is desirable. The pressure range for manufacture

of reducing gas is currently 0.3 – 0.5 MPa, but efforts are in progress to achieve ore reduction at ca. 2 MPa.

3.2.4. Submerged Flame Process

The BASF submerged flame process is also a partial oxidation process; it was developed to produce acetylene (→ Acetylene, Chap. 4.2.3) and ethylene from natural gas and crude oil. Its distinctive feature is maintenance of a flame beneath the surface of the oil sump, to ensure high temperature and short residence time. Hot gases produced by partial combustion and cracking, which have a temperature of ca. 1500 °C, are quenched almost instantly to 250 °C in the hot oil sump. Thus, the thermodynamic equilibrium for the high temperature is "frozen". As in other partial oxidation processes, soot is formed, which collects in the oil sump and is recirculated to the burner. After condensable cracking products are removed, the cracked gas, which still contains a small amount of soot, is scrubbed with condensate. The condensate is then recirculated to the submerged burner.

The process operates between 0.2 and 1.0 MPa and yields a cracked gas with the following approximate composition, in percent by volume, which can be processed into synthesis gas:

Carbon dioxide	7 – 9	Ethylene	6 – 7
Carbon monoxide	40 – 45	Propylene	1 – 2
Hydrogen	23 – 30	Higher olefins and acetylenes	0 – 5
Methane	4 – 5		

From the residual gas, 3.5 t of ammonia, for instance, can be produced per tonne of acetylene.

3.3. Hydrogenating Gasification

Hydrogenating gasification, like partial oxidation, is a continuous process.

Principles. In contrast to partial oxidation, hydrogenating gasification is not based on combustion of part of the feedstock; instead, a hydrogenation reaction which proceeds exothermically overall takes place with addition of hydrogen. Liquid hydrocarbons are cracked primarily to form methane and ethane. This process, therefore, is beneficial for the production of *fuel gases* with a high heating value: on the other hand, direct manufacture of carbon monoxide- and hydrogen-rich synthesis gas is not possible [46].

Gas Recycle Hydrogenator (GRH) Process. The British Gas Corp. began to develop the GRH process in the early 1960s [47]. This enables the conversion of liquid hydrocarbons with a final boiling point up to ca. 325 °C to a gas mixture consisting mainly of hydrogen, methane, and ethane under controlled temperature and pressure in a shaft reactor, termed the

hydrogenator. Hydrogenating gasification produces no soot. The reaction takes place at 1.8 – 7.0 MPa and 350 – 500 °C at the inlet or ca. 750 °C at the outlet, depending on the boiling range of the feedstock. The latter must contain a certain amount of sulfur (about 10 ppm), which acts as a poison on reactor components made of nickel alloy, to prevent them from acting as catalysts that might lead to soot formation from the hydrocarbons. After desulfurization, aromatics removal and methanation, an SNG may be produced with a higher heating value (HHV) of 39 100 kJ/m^3, and a pressure of 6.0 MPa. The thermal efficiency of the process is 85 %.

Fluidized-Bed Hydrogenation (FBH) Process. The FBH process, also developed by the British Gas Corp., enables gasification of crude and extremely heavy oils. Feed oil and hydrogen are superheated and fed into the FBH reactor, in which hydrogenation of the hydrocarbons takes place in a fluidized bed formed from coke between 700 and 820 °C. The most important process variables are temperature, residence time, and oil: hydrogen ratio. Part of the hydrogen is supplied to the reactor through a grate from below to fluidize the coke.

Most of the hydrogen is mixed with the oil and sprayed from below into a central tube. By this means, rapid circulation is achieved in the reactor. The oil evaporates at the outlet of the spray nozzle. Any oil that does not evaporate adheres immediately to the flowing coke particles and is entrained with them. If the raw material contains residue-forming components, coke particles are also formed. Therefore, a small amount of coke must continually be withdrawn from the reactor.

Gas leaving the reactor is quenched with light aromatics, and the condensate is removed from the rich gas. Most of the sulfur in the oil is converted to hydrogen sulfide. A gas produced from Algerian crude with the addition of ca. 6.5 kg of hydrogen per kilogram of oil has a HHV of 39 400 kJ/m^3 at a pressure of 5.0 MPa. For SNG production, gas from the FBH plant must undergo a second hydrogenation step to reduce its hydrogen content [48]. More details on both processes, GRH and FBH, may be found in [49].

4. Gas Production from Coal, Wood, and Other Solid Feedstocks

This chapter deals with the production of gases from solid carbonaceous materials such as *coal*, *peat*, *wood*, *solid wastes* and solid residues from petroleum upgrading (*delayed coke*, etc.). The gasification process occurs via pyrolysis reactions (thermal decomposition) and subsequent heterogeneous (gas – solid) reactions of the solid residue from pyrolysis with reactive gases (O_2, steam, CO_2, H_2).

Besides carbon, solid feedstocks contain other elements such as hydrogen, oxygen, nitrogen, sulfur, heavy metals, and trace elements in varying amounts. The feedstocks are converted to a gaseous product suitable for use either as a source of energy or as a raw material for the synthesis of chemicals and liquid or gaseous fuels. The gaseous product can be handled with maximum convenience and purified easily from compounds that would cause pollution problems. Thus, gasification is an upgrading process that greatly extends the uses of solid fuels.

During their long history, the science and technology of solid feedstock gasification have advanced in various stages induced by external factors. At first directed toward the production of fuel or town gas for lighting and heating, the interest in gasification shifted in the first half of this century to synthesis gas for the production of chemicals and liquid motor fuels.

After a period of increasingly intense competition from oil and natural gas, gas production from solid feedstocks has become less important since the 1940s. In the late 1960s and early 1970s, some industrialized countries began to expect natural gas shortages which, together with oil price increases, changed the attitude toward utilization of solid fuels, particularly coal available in many parts of the world. More and more, the finite nature of fossil fuel reserves, the need for conservation, and good resource management became accepted and the significance of the world's coal reserves was recognized. Interest in *coal* utilization increased, primarily in the fields of gasification and liquefaction (→ Coal Liquefaction), and large sums of money became available from governments for the research, development, and demonstration of new processes and the improvement of existing ones. More recently, since large resources of natural
